Notice

Pharmacology is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy become necessary or appropriate. Readers are advised to check the product information currently provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and the contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for the patient. Neither the publisher nor the editor assumes any responsibility for any injury and/or damage to persons or property.

D E D I C A T I O N

This book is dedicated to Elizabeth E. Haaga, daughter of John and Ellen Haaga, who was born on August 19, 1972, and died December 9, 1985. Beth had a disseminated neuroblastoma, which was diagnosed in 1984. She was treated with a bone marrow transplant and died from graft versus host disease and infection. As her parents, we loved her dearly and cherish the memory of her early years when she was well. After the onset of her illness, we came to know that her gentle and loving nature was accompanied by a remarkably strong character. She endured her pain and suffering without bitterness and never sought to hurt those who loved her. Indeed, most incredibly, she tried to lessen our emotional pain even while enduring her physical discomforts. Many authors have marveled at the qualities of children, and although Beth's short life and premature death have left us saddened beyond comprehension, her remarkable courage and sweetness have given us a lasting pride and respect. We remember her lovingly.

Contributors

James J. Abrahams, MD

Associate Professor (Diagnostic Radiology and Surgery) and Director of Medical Studies, (Diagnostic Radiology), Section of Neuroradiology, Yale University School of Medicine, New Haven; Attending Physician, Yale-New Haven Medical Center, New Haven; West Haven Veterans Administration Hospital, West Haven, Connecticut

Preface

The progress in computed imaging over the past 25 years has been remarkable, to say the very least. These new modalities have revolutionized the delivery of health care around the world and improved the lives of innumerable citizens of the planet. The astonishing development of technology has truly spread worldwide so that even people in the remotest country or island have the benefit of imaging (albeit the highest technology still is present in the developed countries). A graphic demonstration of this spread of technology and medical knowledge can be appreciated by noting the new trend to have international interpretation of night-time studies around the world. Medicine now chases the sun in its use of computerized imaging and beams the images between countries so that night-hawk reading services help rationalize radiology care by making the best use of manpower around the world.

The impact of computed tomography (CT) and magnetic resonance imaging (MRI) on medicine can be further appreciated by noting a recent survey of physicians' views on the importance of 30 medical innovations. Fuchs and Sox published an article, titled "Physicians' Views of the Relative Importance of Thirty Medical Innovations in Health Affairs," in September/October 2001. In their survey of 225 leading internists in the United States, the replies showed that 75% of respondents believed CT and MRI were the most significant innovation, followed by ACE inhibitors, angioplasties, statins, and mammography.

The acceptance and wide application have come at a philosophical and pragmatic price and risk to the profession of radiology. While government planners and HMOs have tried to stem the tide of imaging progress, the science and technology have moved ahead with unstoppable momentum. The result of the attempts of these organizations to prevent the application of these new modalities was an ill-conceived movement to limit the training of radiologists during the era of primary-care physician promotion.

By attempting to prevent the use of imaging in health care, they interfered with the natural market forces of manpower supply and demand. The result is the current manpower shortage at a time when the need for imaging grows on a daily basis. The shortage has impaired training programs because faculty required to train radiologists have been enticed into more lucrative positions in the marketplace.

It is quite evident that the role of imaging will continue to grow and provide a positive impact on the health of all citizens. Its future is ensured by the new emphasis by the National Institutes of Health (NIH) on molecular imaging and also the image-guided microsurgery procedures performed with CT and MRI. We are quite proud to note that a radiologist, Elias Zerhouni, MD, has been appointed as current director of the NIH. Furthermore, we are proud that Dr. Zerhouni was a section editor in the third edition of this text.

Figure 1

It is exciting to reflect back on other high technology developments that have occurred, such as aviation (Fig. 1). If one looks at the progress made in aviation since the first flight of the Wright flyer and contrast it with the Space Shuttle, there was an increase in speed of approximately 600 times (42 mph compared to 25,000 mph) in a 100-year period. With CT scanning (Fig. 2), there has been an increase in scan time of almost 1200 times in a 25-year period (7 minutes per single scan compared to 300 msec on current multislice devices).

Figure 2

We are pleased to note the wide application of the new image-guided microsurgical procedures (the term *interventional radiology* is not specific enough or a unique descriptor). Progress in this area will continue and further improve the delivery of health care. Indeed, at the time of publication of this edition, we are even working on methodology using CT procedures to treat mediastinal collections of anthrax-laden lymph nodes in patients with inhalational anthrax. Data are very preliminary, but it seems that the heat from radiofrequency can be used to kill the vegetative forms of anthrax, and other strategies can be used to stimulate spores to germinate and become susceptible to local instillation of polymer-containing antibiotics.

We are especially grateful to all of our colleagues who have contributed to this edition because of the many difficulties they have overcome. Historically, it has always been difficult for authors to find time to contribute high-quality work. During this current period of faculty shortage at university centers, the commitment and dedication to our project required even more effort by our contributors.

We are delighted with the content of this fourth edition and believe it provides the most up-to-date information on MRI and CT. Information about the new, fast-sequence MRI and multislice scanners is provided. We are confident that the readers of this book will be intellectually rewarded.

Preface to First Edition

Since the introduction of computed tomography (CT) in 1974, there has been a remarkable revolution in the medical treatment of patients. The clinical use of CT has had a broad positive impact on patient management. Literally thousands of patients have been saved or their quality of life improved as a result of the expeditious and accurate diagnosis provided by CT. This improvement in diagnosis and management has occurred in all medical subspecialties, including neurological, pulmonary, cardiac, gastrointestinal, genitourinary, and neuromuscular medicine. Aside from the imaging advantages provided, the role of CT in planning and performing interventional procedures is now recognized. It is the most accurate method for guiding procedures to obtain cytological, histological, or bacteriological specimens and for performing a variety of therapeutic procedures.

The evolution and refinement of CT equipment have been as remarkable as the development of patient diagnosis. When we wrote our first book on CT, the scanning unit used was a 2-minute translate-rotate system. At the time of our second book the 18-second translate-rotate scanning unit was in general use. Currently standard units in radiological practice are third and fourth generation scanners with scan times of less than 5 seconds. All modern systems are more reliable than the earlier generations of equipment. The contrast and spatial resolution of these systems are in the range of 0.5% and less than 1 mm, respectively. The sophistication of the computer programs that aid in the diagnosis is also remarkable. There are now programs for three-dimensional reconstructions, quantitation of blood flow, determination of organ volume, longitudinal scans (Scoutview, Deltaview, Synerview, and Topogram), and even triangulation programs for performing percutaneous biopsy procedures.

CT units are now being installed in virtually every hospital of more than 200 beds throughout the United States. Most radiologists using these units are generalists who scan all portions of the anatomy. Because of the dissemination of this equipment and its use in general diagnosis, there exists a significant need for a general and complete textbook to cover all aspects of CT scanning. Our book is intended to partially supplement the knowledge of this group of physicians. We have attempted to completely and succinctly cover all portions of CT scanning to provide a complete general reference text. In planning the book, we chose to include the contributions of a large number of talented academicians with expertise different from and more complete than our own in their selected areas. By

including contributors from outside our own department, we have been able to produce an in-depth textbook that combines the academic strengths of numerous individuals and departments.

The book is divided into chapters according to the organ systems, except for some special chapters on abscesses and interventional procedures. In each of the chapters the authors have organized the material into broad categories, such as congenital, benign, or neoplastic disease. Each author has tried to cover the major disease processes in each of the general categories in which CT diagnosis is applicable. Specific technical details, including the method of scanning, contrast material, collimation, and slice thickness, are covered in each chapter. The interventional chapter extensively covers the various biopsy and therapeutic procedures in all the organ systems. Finally, the last chapter presents an up-to-the-minute coverage of current and recent developments in the CT literature and also provides extensive information about nuclear magnetic resonance (NMR) imaging. At this time we have had moderate experience with the NMR superconducting magnetic device produced by the Technicare Corporation and have formulated some initial opinions as to its role relative to CT and other imaging modalities. A concise discussion of the physics of NMR and a current clinical status report of the new modality are provided.

We would like to thank all those people who have worked so diligently and faithfully for the preparation of this book. First, we are very grateful to our many contributors. For photography work, we are deeply indebted to Mr. Joseph P. Molter. For secretarial and organizational skills, we are indebted especially to Mrs. Mary Ann Reid and Mrs. Rayna Lipscomb. The editorial skills of Ms. B. Hami were invaluable in preparing the manuscript. Our extremely competent technical staff included Mr. Joseph Agee, Ms. Ginger Haddad, Mrs. E. Martinelle, Mr. Mark Clampett, Mrs. Mary Kralik, and numerous others.

Finally, we are, of course, very appreciative of the support, patience, and encouragement of our wonderful families. In the Haaga family this includes Ellen, Elizabeth, Matthew, and Timothy, who provided the positive motivation and support for this book. Warm gratitude for unswerving support is also due to Rose, Sue, Lisa, Chris, Katie, Mary, and John Alfidi.

Imaging Principles in Computed Tomography

Floro Miraldi, Michael S. Sims,
Ernest J. Wiesen

A computed tomography (CT) image is a display of the anatomy of a thin slice of the body developed from multiple x-ray absorption measurements made around the body's periphery. Unlike conventional tomography, in which the image of a thin section is created by blurring out the information from unwanted regions, the CT image is constructed mathematically using data arising only from the section of interest. Generating such an image is confined to cross-sections of the anatomy that are oriented essentially perpendicular to the axial dimension of the body (Fig. 1-1). Reconstruction of the final image can be accomplished in any plane, but conventionally it is performed in the transaxial plane.

In its most basic form, the fundamental principles of CT are the same as those for radiography and tomography. Each approach directs a source of ionizing radiation through an object to recreate an image of the original object based on the x-ray absorption of the object. The basic equation used is the same for each,

$$I = I_0 e^{-\mu x} \quad (1)$$

where

I_0 is the incident intensity of an x-ray beam on the surface of an object of thickness, x

I is the transmitted intensity

e is Euler's constant (2.718)

μ is the linear attenuation coefficient (Fig. 1-2)^{7, 19}

Attenuation is dependent on (1) the atomic number and density of the material through which the x-rays pass and (2) the energy spectrum of the incident x-ray beam.¹⁹ With conventional radiography and tomography, the differential absorption of x-rays passing through an object is recorded on film, a qualitative measurement that cannot accurately reflect subtle differences in object contrast. On the other hand, differential absorption for CT is recorded by special detectors, which are quantitative and can measure subtle changes in x-ray attenuation. Radiography's most major shortfall is the superimposition of the structures on film, which has been only partially overcome by conventional tomography.

The earliest CT was designed by Godfrey Hounsfield to overcome the visual representation challenges in radiography and tomography by collimating the x-ray beam and transmitting x-rays only through small cross-sections of an

object. The idea revolutionized the practice of radiology and helped win Hounsfield a share of the Nobel Prize. More recent CT developments since the mid-1980s have advanced CT from a radiology tool limited to anatomic representations to a tool capable of demonstrating physiologic and pathogenic information.

This chapter presents the physics of CT image production in qualitative terms to familiarize the practicing radiologist with the basic principles of CT. Equipment and factors that affect CT image quality are discussed, and an introduction to emerging applications using CT is provided.

Basic Principles

The fundamental concept of CT is that the internal structure of an object can be reconstructed from multiple projections of the object (Fig. 1-3). The object in Fig. 1-3A is composed of a number of equal blocks from which the central four have been removed to represent an internal structure. For the sake of simplicity, assume that an x-ray beam is passed through each row and column of blocks and the transmitted radiation is measured. Since each block is the same, the measured attenuation is proportional to the number of blocks encountered in each row or column.

The numbers shown at the right and beneath the object represent the relative measured attenuation (i.e., the number of blocks in each row or column). These attenuation measurements are then added (Fig. 1-3B) to produce a numeric representation of the object (Fig. 1-3C). Although this array of numbers contains all the information of the process, it is difficult to interpret; thus, the array is converted into picture form by assigning a gray scale to the numbers. Large numbers are represented by light shades of gray, and small numbers are represented by dark shades of gray. The result is the image shown in Figure 1-3D. The resultant image can then be manipulated to highlight certain areas. For example, if the gray scale is narrowed to include only black and white, a perfect reproduction of the object is obtained by assigning black to all numbers equal to four or less and white to all numbers greater than four.

In Figure 1-3E, an imperfect representation is obtained because the gray scale is chosen so that values of six and lower are black and values above six are white. In CT, the method of obtaining the array of numbers is more complex

Figure 1-1. A CT image represents anatomy of a transaxial slice of the body obtained from many transaxial attenuation measurements.

and the number of projections obtained is much greater; however, the principle is the same.

The example of Figure 1-3 also provides a basis for a number of definitions of CT terms. Each of the blocks in Figure 1-3A represents a small attenuating volume of material and is referred to as a *voxel*. The numbers at the side and bottom of Figure 1-3A represent single attenuation measurements and are called *ray projections*, or *ray sums*. The array of numbers in Figure 1-3C is a *matrix*, and the individual numbers are elements of that matrix.

Each of the blocks of gray that are used for the construction of the images in Figure 1-3D-F is a picture element (*pixel*). The process of choosing the number of gray shades for a display is referred to as "selecting a window." The width of the window (Fig. 1-3E and F) is narrow because it only contains two shades of gray (black and white) compared with the wider window in Figure 1-3D, which contains three shades of gray. The number at which the

window setting is centered is called the *window level*. In Figure 1-3E, the level is set at four; in Figure 1-3F, it is set at six.

To present attenuation data (either I or μ) at every point throughout the body would be ideal in an x-ray examination. The degree to which this is attained depends on the manner in which the measured intensities, I and I_0 , are registered or manipulated. In conventional radiography, the transmitted intensity (I) is seen as the darkening of a film. Because x-ray exposure of the film blackens it, the image of a dense object is lighter on the film than the image of a less dense material. In a typical radiographic film of the chest, for example, the image is light where many x-rays are absorbed or scattered (large μ), such as in bone, and dark where many x-rays are transmitted because of low absorption (small μ), such as in the regions of the lung parenchyma.

Two different areas of such a chest film may show the same darkening and therefore demonstrate equal total attenuation of the beam in the two positions. However, the attenuation profile through the body may be quite different. This is diagrammatically shown in Figure 1-4, with one beam passing through a region of relatively uniform density and the other beam passing through a region of nonuniform densities.

In conventional radiography, therefore, the different shades of gray seen on the film represent the differences in the transmission of an x-ray beam as it passes through the body. CT, however, approaches the ideal by presenting the average attenuation of each small volume element that comprises the body slice. Thus, CT unscrambles the attenuation information of the x-ray beam and presents it quantitatively with accuracy far greater than that accomplished by conventional techniques. This is equivalent to providing the individual values μ_1 , μ_2 , and μ_3 of Figure 1-4 rather than the total value described for conventional radiography.

All CT systems use a similar three-step process to generate a CT image: (1) scan, or data acquisition, (2)

Figure 1-2. Exponential behavior of x-ray beam attenuation.

Figure 1-3. Principle of image reconstruction. (From Christensen EE, Curry TS III, Dowdey JE: An Introduction to the Physics of Diagnostic Radiology, 2nd ed. Philadelphia, Lea & Febiger, 1978.)

reconstruction, and (3) display; each process is considered separately throughout this chapter. In the most basic form, the flow of all CT systems includes the conversion of an x-ray source consisting of a collection of rays (*projection* or *view*). A single ray is considered the portion of the x-ray beam that falls onto one detector.

Data Acquisition

The scanning process begins with data acquisition. CT scanning is the systematic collection of projection data. Data collection encompasses all of the geometric properties of the x-ray beam and the relationship of the x-ray tube to the detector, including all of the beam-shaping devices and conversion of transmitted x-rays to digital signals for use by the reconstruction system. Since Hounsfield's invention, CT scanning geometry has evolved considerably. Before

we address the evolution of CT data acquisition and CT scanning geometry, it is valuable to review the basic components of every CT data acquisition system.

Components of a Data Acquisition System

Scan Frame

Early CT scanners (in the 1980s) deployed rotating frames and recoiling system cables. This design was limited to step-and-shoot scan methods and considerably limited scanner rotation times. Current systems employ slip rings, electromechanical devices that transmit electrical energy across a rotating surface. Slip rings permit the scan frame to rotate continuously, enabling spiral or helical CT scanning and eliminating the need to rewind system cables.

Figure 1-4. Total attenuation of equal amount in two different cases. A, Nonuniform attenuation coefficients. B, Uniform medium.

X-ray Generators

Most CT scanners today use high-frequency generators to produce x-ray quanta required for today's demanding CT protocols. Typical operating frequencies range from 5 to 50 kHz. Generator power can range from as low as 15 kilowatts (kW) to as high as 60 kW, and recent developments are likely to support ranges as high as 70 to 80 kW. In any case, most generators support a wide range of exposure techniques from 80 to 140 kilovolts (kV) and 30 to 500 milliamperes (mA). The generators are located on rotating scan frames within the CT gantry to accommodate new spiral scanning requirements.

X-ray Tubes

Early-generation CT technology used fixed-anode, oil-cooled x-ray tubes with fairly limited capability. Today's x-ray tubes include rotating anodes with unique cooling methods designed to enhance a system's ability to cover large areas of anatomy at diagnostic levels of x-ray output. Tube ratings typical in CT scanners today vary from 2 million heat units (2 MHU) of storage capability, with 300 thousand heat units (kHU)/minute cooling, up to 7 MHU of anode heat storage capability and cooling rates as fast as 1 million heat units (MHU)/minute. Future enhancements will not preclude tubes with greater than 10 MHU capacity and continuous output power capability of 60 kW. Both x-ray generator and x-ray tube developments are expected to open up the door for true volumetric CT applications with large area detectors designed to cover entire sections of patient anatomy within one revolution of the CT scanner's rotating frame.

X-ray Beam Filtration System

It is assumed that CT employs a monochromatic beam. The opposite is true; radiation from CT x-ray tubes is polychromatic. To compensate for this fact, the x-ray beam is shaped by *compensation filters*. The filters serve two purposes:

1. They remove the long-wavelength x-rays, which do not contribute to the CT image but do contribute to patient dose as these so-called soft rays are absorbed by the patient.
2. They serve to minimize the effects of beam hardening and provide a more uniform beam, as seen from the perspective of the detector.

Different filters are used for half-field (head) scanning and full-field (body) scanning. Additional corrections for beam hardening are made during the CT reconstruction process with software.

Data Acquisition Systems

Data acquisitions systems are the heart of a CT scanner. They include (1) the detector system, (2) analog-to-digital conversion, and (3) some data preprocessing for use by the scanners reconstruction system. The major functions are as follows³⁴:

- To convert x-ray flux to electric current
- To convert electric current to voltage
- To convert analog voltage to digital form

- To subtract background offset signal
- To provide logarithmic conversion of data
- To transmit data to the preprocessing system

Early data acquisition systems employed xenon (gas ionization detectors). These detectors directly convert x-ray energy to electrical energy but are inefficient. Most modern systems include the use of solid-state detectors. Two primary crystal materials are in use today, cadmium tungstate and gadolinium oxysulfide. The crystals convert the x-rays to light proportional to the quantity of photons striking the crystal. The light is converted to current and hence a voltage across a resistance and then to digital data for use by the reconstruction system.

The conversion of analog signals to digital data (A to D conversion) by the data acquisition system creates a *quantization error*. Sampling speed of the A to D converter and the number of digital output combinations available determine quantization error. This quantization error, along with electronic noise in the amplifier, generally characterizes the performance of the data acquisition system. The system's ability to measure low-level signals accurately over a wide dynamic range largely contributes to CT's overall image quality capabilities per a given x-ray flux.

Evolution of Data Acquisition Systems and CT System Geometry

First-Generation System

First-generation CT data acquisition was based on parallel-beam geometry with a translate-rotate principle of the tube/detector combination. The x-ray beam was collimated to dimensions of roughly 2×13 mm. The 13-mm dimension corresponded to the slice thickness (voxel length). Small detectors monitored the intensity of the beam before entering the body to yield the value of the incident intensity (I_0). After passing through the body, the beam was detected by a scintillation crystal, collimated to receive, primarily, those photons that were not scattered or absorbed. The amount of transmitted intensity (I) was then recorded and stored in the computer memory.

The x-ray tube and detector system were moved continuously across the patient, making 160 multiple measurements during the translation. At the end of each translation, the x-ray tube and detector system were rotated 1 degree and the translation repeated. The translate-rotate process was repeated for 180 translations, yielding 28,800 (160×180) measurements. The 160 measurements made during one complete translation are called a *profile* or *view*.

From a clinical standpoint, the first-generation machine had the major disadvantage of long scanning times. Image quality severely suffered from the effects of patient motion, since 5 minutes was required to gather the 28,800 ray sums. This disadvantage limited use to body parts such as the head, which can be made immobile.

Second-Generation System

Second-generation data acquisition and scanner geometry included fan-beam reconstruction with a linear detector array. The x-ray beam was converted to a fan shape with a

Figure 1-5. Translate-rotate scanner. A, Original single-detector system, single translation. B, Two separate translations. C, Second-generation system with fan beam source and multiple detectors.

diverging angle of between 3 and 10 degrees (Fig. 1-5). Multiple x-ray detectors were then placed adjacent to each other to intercept this beam. Because more x-ray detectors were used with this system, the number of angular rotations could be decreased and an adequate number of views obtained in much shorter intervals. With second-generation data acquisition, scanners could obtain a scan in periods as short as 18 seconds. From Figure 1-5, it is obvious that each detector obtains a different view during a translation because the rays from the x-ray tube to the detectors are not parallel.

The next few developments in CT involved a widening of the fan beam so that it encompasses the object entirely.

Third-Generation System

Third-generation data acquisition and scanner geometry use wide-angle fan beam geometry (50 to 55 degrees); an arc of detectors and an x-ray tube rotate continuously around the patient for 360 degrees. As the x-ray tube and detector arc are rotated, projection data (or data samples) are obtained, and for every fixed point of the tube and detector, a view is created (Fig. 1-6).

As Figure 1-6 demonstrates, the detectors are fixed

radially and do not view the scan area uniformly. Only the center detectors in the array “see” the pixels at the center of the *field of view* (FOV). However, this fixed relationship allows the detectors to be highly collimated, which greatly reduces scatter radiation; as discussed later, this also reduces “image noise” (mottle, or grainy background) and improves image quality.

As a result of the fixed position of the tube/detector combination the associated detectors and electronics system must be stable, uniform, and capable of tracking over a wide dynamic range. Noncompensation for errors as small as a few thousandths of 1% can cause visible (ring) artifacts (see Fig. 1-39). In addition, spatial resolution, a key image quality parameter of CT (see later), can be limited by the data sampling. In this geometric relationship, the number of detectors in the arc or array determines data sampling; that is, spatial resolution depends on how closely spaced the rays are in each view.

The typical number of detectors ranges from about 600 to more than 900. These numbers result in a limiting spatial resolution of approximately 5 to 10 line pairs per centimeter (lp/cm), depending on the reconstruction matrix size and scan FOV. Sampling theory (Nyquist) requires that to visualize a particular frequency, the sampling frequency must be at least twice that value. In practice, even higher sampling rates are desirable. Axial resolution of greater than 5 to 10 lp/cm (0.5 to 1.0 mm) may be limiting for specific clinical applications.

To overcome this challenge, manufacturers have introduced various methods. One method of increasing sampling (and spatial resolution) is to offset the detector array relative to the center of rotation by a quarter-ray or eighth-ray. This permits data collected during the second half of a 360-degree rotation to be interleaved with that of the first half, effectively doubling the sampling and resolution. Unfortunately, patient motion can minimize this effect. In addition, this method is restricted with spiral CT scanning (see later) to certain modes in which 360 degrees of data is available for interleaving.

Another more effective method of increasing data sampling is to scan or oscillate the x-ray tube focal spot a few millimeters during a scan (Fig. 1-6B) in order to achieve interleaved data samples. The position of the focal spot is accurately controlled and synchronized with rotational speed and position of the rotating frame.

Spatial resolution also requires adequate view sampling to prevent “aliasing” artifacts. Views in this case are limited by the electronic measurement capability of the scanner, which is typically not the gating factor for maximum resolution. These factors vary for every CT manufacturer, which can dramatically affect the overall performance of a scanner.

Fourth-Generation System

Fourth-generation data acquisition and scanner geometry (Fig. 1-7) also use a wide-angle rotating fan beam (50 to 55 degrees); in this case, though, the tube rotates within a 360-degree arc of stationary detectors. Instead of the focal spot as the focus of views, as in a third-generation system, views are seen from the perspective of the detector. With

Figure 1-6. A, Third-generation rotate-only scanner geometry showing fixed relationship of x-ray tube and detectors. B, Dynamic focal spot technology (Marconi Medical Systems) effectively doubles the data sampling rate.

this approach, data samples are obtained over the width of the fan angle and several data samples are acquired per detector. The output of each detector constitutes a view. Therefore, views are limited to the number of detectors in the 360-degree arc.

In this geometric configuration, data sampling is limited by the system electronics, not by the number of detectors. The collection of equivalent, closely spaced ray sums using

this geometry permits a very high spatial resolution (>20 lp/cm) (Fig. 1-8),²⁸ although it forces a wider collimation of the detector, which in turn can cause an increase in detection of scattered radiation. Several techniques are employed to minimize the effect of scattered radiation. Most important, natural rejection of scatter is minimized with appropriate distance between the patient and detectors.

With fourth-generation geometry, small, closely spaced

Figure 1-7. Fourth-generation scanner geometry, Model PQ6000 (Marconi Medical Systems). Views are seen from the perspective of the detector.

Figure 1-8. Overlapped measurements. Leading edge of the x-ray beam is shown at three different times (T1, T2, and T3), representing small, closely spaced data samples during a scan.

data samples require many individual measurements, which can affect reconstruction time. To overcome this challenge, views are averaged to reduce this effect. Most systems have many more detectors and views available to exceed the limiting resolution of the system.

There are unique advantages and disadvantages to today's CT geometry beyond spatial resolution, including (1) detected quantum efficiency, (2) noise, and (3) contrast resolution. The performance of each system depends largely on the manufacturer and not the scanning geometry used.

Spiral/Helical Computed Tomography

Until the late 1980s, CT scanners, regardless of system geometry (third or fourth generation), acquired data in discrete slices of patient anatomy in a method commonly called *axial scanning*. In axial (cross-sectional) CT, each revolution of the x-ray tube around the patient produced a single data set (*slice*). During data collection, the patient table is motionless. To create an additional slice, the table is indexed a given amount and the x-ray tube is once again rotated around the patient. Each rotation or slice produces a single image. The advent of slip ring technology and new data reconstruction techniques provided a gateway to the data acquisition currently in use namely, (1) spiral/helical CT and (2) multislice spiral or multidetector/multirow CT data acquisition systems.

In spiral/helical CT, the patient table translates through the gantry while the x-ray tube (fourth generation) or the x-ray tube/detector combinations (third generation) rotate continuously around the patient, creating a volume of data. This permits new options in reconstruction. For example, once a volume of data is collected, an image can be reconstructed at any point along the effective path traced by the x-ray tube. At this point, it may be helpful to define the terms associated with spiral scanning (Table 1-1):

Acquisition is the entire volume of data collected during a continuous spiral scan.

Revolutions refer to the number of 360-degree rotations of the x-ray tube during a single acquisition.

Pitch is the distance the couch travels during one 360-degree revolution of the x-ray tube.

Table 1-1. Spiral Scanning Terms in Computed Tomography

Acquisition (spiral)	The process by which a single, continuous volume of computed tomography data are acquired without a pause
Revolution	One per each 360-degree rotation of the x-ray tube around the patient or object of interest
Pitch	The distance the couch or patient travels through the gantry during one 360-degree beam rotation
Pitch factor	A unitless parameter in which pitch can be designated. This is defined as the pitch (mm) divided by the collimated slice thickness (mm)
Interpolation	A mathematical technique used to estimate the value of a function from values on either side of it

Figure 1-9. Extending the pitch factor from 1:1 to 1.5:1 increases volume coverage by 50% and decreases patient dose by 33%.

Pitch factor is the pitch divided by the collimated slice thickness, or effective width of the beam at the isocenter of the gantry. The term "pitch" has become synonymous with "pitch factor."

Interpolation is a reconstruction method (most accurately described as "deconvolution") that permits the realignment of spiral/helical scan data for reconstruction of an axial (cross-sectional) slice.

Spiral CT has many advantages over conventional or axial CT, including³⁰:

- The ability to minimize motion artifacts
- Decreased incidence of misregistration between consecutive axial slices
- Reduced patient dose
- Improved spatial resolution in the z-axis
- Enhanced multiplanar (MPR) or three-dimensional (3D) renderings

The ability to minimize motion artifacts in spiral CT is due to the faster scan times associated with every examination (versus step-and-shoot axial scanning) and the ability for many spiral CT examinations to be completed in a single patient breath-hold.

The faster scan times associated with spiral CT also permit accurate slice-to-slice registration and eliminate misregistration associated with inconsistent breath-holds related to conventional axial scanning. Reconstructions can be overlapped or ideally positioned for accurate visualization of small lesions.

Spiral scanners achieve reduced patient dose by extending the pitch factor for a given study. For example, consider a typical thorax, abdomen, or pelvis examination. Typical slice widths range from 5 to 10 mm. With spiral CT, the same examination can be completed with a given slice thickness as conventional CT with 50% greater table speed using a pitch of 1.5; this results in a 33% reduction in patient dose (Fig. 1-9). The nominal downside to this

approach is a slight broadening of the slice sensitivity profile (effective axial slice thickness) based on the type of spiral reconstruction chosen. The slice thickness formula is given as³²

$$\sigma = \frac{D^2}{12} + \frac{T^2}{24} \quad (2)$$

where

D is detector collimation

T is table speed

σ is the standard deviation (SD) of the slice sensitivity profile

See "Reconstruction" for further details.

With continuous collection of data, as just described, spiral CT enables a reduction in image-to-image separation, thus improving spatial resolution in the z-axis. Although conventional CT might overcome this challenge by overlapping consecutive axial slices, this would increase the patient radiation dose and would lengthen scan times to cover a given region of patient anatomy.

Multiplanar and 3D renderings are enhanced as a result of the ability of spiral CT to reconstruct overlapped planar and axial slices from a continuous volume of data. The optimal number is two to three transverse slices per detector collimation³² and is given as the formula

$$n = \frac{3}{\pi \sqrt{\frac{1}{12} + \frac{p^2}{24}}} \quad (3)$$

where

n is the slice number per collimation

p is pitch (table speed over collimation)

Spiral CT data acquisition systems must be capable of collecting large volumes of data at extremely fast data rates. Data sampling for most systems is in the range of 3 kHz and can provide up to nearly 2400 projections or views per rotation of the gantry. Data rates for many new systems exceed 200 megabits/second. This extremely fast sampling capability enables high spatial resolution and enhanced z-axis sampling of patient anatomy.

The increased speed of data acquisition systems and a number of other technologic developments paved the way for data acquisition at subsecond rotation speeds of the rotating frame. Subsecond spiral data acquisition permits temporal resolution on the order of 250 to 480 msec, depending on the manufacturer. Temporal resolution of this magnitude enables more examinations to be accomplished within a single breath-hold and dramatically improves the anatomy that can be covered in a single scan. This improves clinical applications such as CT angiography, which requires precise timing of a bolus injection and rapid acquisition during the arterial phase. Subsecond data acquisition also can improve the z-axis resolution (slice thickness) for a given study by covering the same amount of anatomy in the same time with thinner slices. However, spiral CT is not without limitations and many examinations might benefit from an even more dramatic increase in data acquisition rates.

Multislice Spiral CT

The latest development in data acquisition—multislice spiral CT—overcomes the limits of spiral CT. All multislice spiral CT systems today use third-generation geometry (rotate only) with the added dimension of multiple arcs of detectors. The first deployment of this technology included a dual-arc detector (Fig. 1-10).³⁸ In this configuration, two parallel arcs of detectors are used to simultaneously acquire data during a single revolution of the scan frame, dividing the total x-ray beam into two equal beams described by the detector aperture of each row of detectors. Considering small gaps between rows, which can be ignored from the perspective of data acquisition, the total x-ray beam collimation now becomes the sum of detector row collimations (Fig. 1-11) and is described as

$$d(\text{mm}) = \frac{D(\text{mm})}{2} \quad (4)$$

where

d is the detector row collimation

D is the x-ray beam collimation

2 is the number of detector rows

This can be extended to include n rows of detectors.

Four-Slice Design

Since the introduction of dual-detector technology in the early 1990s, other manufacturers have introduced four-slice configurations. Two four-slice design approaches are described.

Equal-Width Detector

As with the dual-beam array, detectors of equal widths are stacked back to back in the z-axis (Fig. 1-12). In the case of one manufacturer, 16 rows of 1.25-mm detectors (effective width at isocenter) are aligned in the z-axis. To achieve different slice widths, the detectors are electronically coupled at the beginning of each scan according to the requested slice width. The total z-axis dimension of the detector covers 20 mm. This approach limits the minimal z-axis resolution to the nominal width (at isocenter) of the individual detectors. Figure 1-13 demonstrates the use of multiple detector combinations per requested slice width.

Variable-Width Detector

A second approach (Fig. 1-14) combines fewer detectors of variable widths and a postpatient collimator to define slice widths. This approach is more geometrically efficient because there is less unusable space in the z-axis (Fig. 1-15A). This combination also permits slice widths as small as 0.5 mm, enabling isotropic imaging (submillimeter voxel dimensions are equal in all planes) (Fig. 1-15B).

In either case, the clinical benefits of multislice CT can best be described by comparing clinical protocols versus single-ring spiral CT. For a given protocol, multislice CT is more efficient by the number of detector rings used. Consider a typical single-slice spiral CT protocol of 40 seconds, at 1 second per revolution (scan time), with a slice thickness of 5 mm, using 200 mA, with 200 mm of

Figure 1-10. The first multislice detector system (Marconi Medical Systems dual-arc detector). Two detectors are aligned consecutively in the z-axis, creating a 2D detector matrix/array and two images per gantry revolution. (Courtesy of J. S. Arenson.)

Figure 1-12. Multislice spiral CT Matrix detector (GE Medical Systems) with 16 rows of equal width (1.25 mm at isocenter) detector elements.

Figure 1-13. Matrix detector. Electronic combination of individual elements produces slice collimation configurations of 4×1.25 mm, 4×2.5 mm, 4×3.75 mm, and 4×5 mm.

Figure 1-14. Asymmetrix variable detector array (Marconi Medical Systems) and postpatient collimator produces slice collimation configurations of 2×0.5 mm, 4×1 mm, 4×2.5 mm, and 4×5 mm.

Figure 1-15. A, Comparison of z-axis geometric efficiency of multislice CT detectors. At wide collimations, variable detector array is more efficient. B, A 2×0.5 -mm slice width with ultrahigh in-plane resolution produces isotropic imaging; voxel width is equal in all dimensions.

total anatomic coverage. Using a multislice data acquisition system with n rings, the same protocol can be modified to:

1. Enhance z-axis resolution by a factor of n . The slice thickness is divided by n rings with the same total anatomic coverage, scan time, and milliampereseconds (mAs).
2. Enhance the speed of anatomic coverage by n . The 40-second continuous spiral run is divided by n , with the same nominal slice thickness, scan coverage, and mAs.
3. Enhance the anatomic coverage of the examination by n ; 200 mm of coverage is multiplied by n using the same nominal slice thickness, scan time, and mAs.
4. Increase effective milliamperage by n . By dividing the pitch by n rings, the 200 mAs is effectively increased by a factor of n , maintaining the same nominal slice thickness, scan time, and coverage.

As described earlier, pitch or pitch factor is the distance in millimeters the couch is moved during one revolution of the gantry. Pitch is determined by dividing the movement of the table through the gantry during one 360-degree rotation by the x-ray beam collimation at the source (prepatient collimator). By segmenting the usable x-ray beam into n segments, multislice CT complicates the equation.

There are two commonly used definitions (Fig. 1-16):

1. Pitch is defined using the model described earlier; however, a prefix added to the pitch indicates the number of detector rings used (e.g., single, one ring; dual, two rings; quad, four rings). A pitch of quad-1 would refer to a scan in which the table moves the distance of the source (prepatient) collimation during one revolution of the gantry. For a given protocol, a pitch 1 scan delivers the same patient dose and fundamentally produces the same image quality in a single-slice, dual-slice, or quad-slice scanner.
2. Pitch is defined as the result of dividing the movement of the table through the gantry by the effective slice width at the isocenter of a single detector (or n rings \times effective slice thickness of an individual slice). Thus, a pitch of 4 is equivalent to a quad-pitch 1 (see first definition).

An accepted convention will emerge, but at first glance it appears that the second definition is confusing and offers

less information. For example, from definition 2, a pitch 2 could refer to single-pitch 2, dual-pitch 1, or quad-pitch 0.5.

As of this writing, several manufacturers have introduced four-slice models, but future configurations of 8, 16, 32, 64, and perhaps even flat panel detectors of several hundred square millimeters are on the horizon.

In each case, multislice CT complicates fan-beam reconstruction techniques by adding a divergence of the fan beam along the longitudinal axis (z-axis), creating a cone shape (cone beam) (Fig. 1-17). This new technique, *cone-beam reconstruction*, is considered later (see "Reconstruction").

Electron Beam Computed Tomography

A modification of the fourth-generation concept of data acquisition involves moving the x-ray beam electronically instead of mechanically. This scanning method reduces the scan time to approximately 0.02 second per slice and, with a small delay for consecutive slices, up to 17 slices per second.

An electron beam is accelerated along the axis of rotation of the CT scanner and is electronically deflected to any one of four fixed tungsten x-ray targets. Each target is an arc of tungsten of 210 degrees with a radius of 90 cm. The electron beam is deflected through the 210-degree arc of the target, creating the scan.

Opposite the target are two sets of stationary detectors with arcs of 216 degrees. One detector arc has 432 detectors; the other, a higher-resolution ring, has 864 detectors. Each individual detector consists of a cadmium tungstate crystal matched with a silicon photodiode and a preamplifier. Adjacent detectors of the high-resolution ring can be summed to match the other ring for dynamic imaging, or can be used singly, for high-resolution imaging.

During dynamic scanning, two slices can be acquired simultaneously. Scanning takes place over 180 degrees instead of the 360 degrees of most conventional scanners. An image can be reconstructed with 180 degrees of data.

Once the signals are generated, the remainder of the scanner is fairly conventional in design. This system design has many image quality shortfalls for routine imaging, but its superior temporal resolution has led the way for CT into the realm of cardiac imaging.²⁴

Figure 1-16. Naming conventions for pitch. A, Single-ring spiral CT definition in which pitch equals table speed/source collimation. B, Alternative definitions for multislice spiral CT, with definition 1 representing table speed/source collimation as quad-pitch 1 and definition 2 representing table speed divided by the single-slice collimation (detector collimation) as pitch 4. Both are accepted.

Figure 1-17. The x-ray fan beam is divergent in the z-axis, creating a cone beam.

Reconstruction

Reconstruction includes all of the system components necessary to perform the mathematical computations that are required to convert the digital data (representing the log of attenuation coefficients) provided by the data acquisition system. The reconstruction system delivers CT data to the display system in a manner that is suitable for viewing on a viewing monitor. Regardless of the scanner type, the result of a scan is a large number of individual ray sums. The reconstruction of the image from these measurements is, in principle, the same for every CT scanner.

The fundamental equation describing the behavior of the measurements is given in Equation 5, and a few simple manipulations of this relationship should help one to understand CT image reconstruction.

Figure 1-18 shows a number of thin slabs with an initial x-ray intensity (I_0) impinging on the first slab. The exit intensity from the first slab (I_1) becomes the entrance intensity for the second slab, and its exit intensity (I_2) is the

Figure 1-18. Illustration of Equation 6 (see text).

entrance intensity for the third slab, and so forth. We can then write

$$\begin{aligned} I_1 &= I_0 e^{-\mu_1 L_1} \\ I_2 &= I_1 e^{-\mu_2 L_2} = (I_0 e^{-\mu_1 L_1}) e^{-\mu_2 L_2} \\ I_n &= I_{n-1} e^{-\mu_n L_n} \end{aligned} \quad (5)$$

The equation for the emergent beam after passing through n slabs can then be deduced as

$$\begin{aligned} I &= I_0 (e^{-\mu_1 L_1}) (e^{-\mu_2 L_2}) \dots (e^{-\mu_n L_n}) \\ &= I_0 e^{-\mu_1 L_1 - \mu_2 L_2 - \dots - \mu_n L_n} \end{aligned} \quad (6)$$

For simplicity, the subscript n on I_n has been dropped. Therefore, the total attenuation is equivalent to the simple equation

$$I = I_0 e^{-\mu L} \quad (7)$$

where

$$\mu L = \mu_1 L_1 + \mu_2 L_2 + \dots + \mu_n L_n \quad (8)$$

When $L_1 = L_2 = L_3 = \dots = L_n$ (i.e., all the slabs have equal thickness), Equation 8 can be written as

$$\mu L = (\mu_1 + \mu_2 + \dots + \mu_n) L$$

If we now take the natural logarithm (\ln) of both sides of Equation 7 and rearrange it, the result is

$$\mu = (\mu_1 + \mu_2 + \dots + \mu_n) = \frac{1}{L} \ln \frac{I_0}{I} \quad (10)$$

Equation 10 shows that, if the incident intensity I_0 , transmitted intensity I , and segment length L are known, the sum of the attenuation coefficients along the path of the x-ray beam can be calculated.

Because there are n unknowns (one of each segment), each value of the attenuation coefficient cannot be determined from a single equation. Algebraic theory requires that there be n independent equations to obtain solutions for the n unknown values of μ . To get n independent equations, a number of views must be taken; it is then possible to gather sufficient data for the multiple equations.

A comparison with conventional radiography shows that because only one measurement is made in radiography, only the average value of μ or the sum of the μL s can be obtained. Thus, the information on the film is less detailed than the information on a CT image.

Reconstruction Process

For each ray projection measurement made during a CT scan, Equation 10 is generated and the complete set of such equations must then be solved to obtain the individual values of μ for each matrix element. Because thousands of ray projections are obtained for a scan, thousands of equations must be solved simultaneously and the need for high-speed computers is obvious.

Note that L is not related to the slice thickness (voxel length) and is chosen for the reconstruction process by selecting a matrix size. Provided that sufficient ray projections have been made, the image can be reconstructed in any matrix size, which is paramount to choosing any value of L . The voxel length is set by the collimation of the scanner when a slice thickness is selected. A picture element (pixel), therefore, represents the attenuation coefficient (μ) of a volume element with length determined by the slice thickness chosen during the data acquisition and cross-sectional area that has a side dimension (L) chosen at the time of reconstruction.

Many methods have been devised to solve the set of equations generated in a scan; however, most manufacturers have settled on the filtered back-projection method because it allows short computation time with relatively accurate solutions.^{2,4,5,8,9} It also allows processing of each ray sum immediately after it is obtained while the data acquisition continues for other ray sums. This permits the final image to be available for viewing almost immediately after completion of the scanning process. It is important to understand the basic concepts underlying reconstruction procedures, since their manner of application affects the quality of the final image.

The back-projection method is an attempt to approximate the solution by projection of a uniform value of attenuation over the path of the ray such that the calculated attenuation over the path is proportional to the measured

attenuation. These values are then stored in the computer for the matrix elements involved, and the process is repeated for each ray sum of the scan. Each matrix element thus receives a contribution from each ray that passes through it. For those voxels through which the beam passes obliquely, a correction is made to the contribution (Fig. 1-19). The final image obtained is rather blurred as a result of the assumption that the beam attenuation occurs uniformly over the entire path of the ray.

The process is exemplified in Figure 1-20, which demonstrates the result of applying this procedure to a uniform field with a circular object of high-density embedded in it. In the example, only a few rays are used.

Two observations should be made: (1) the procedure generates a star pattern, and (2) it tends to approximate the image better as more views are obtained.

No matter how many views are used, however, the blurring effect is never completely eliminated. Thus, a second mathematical maneuver called a *convolution operation*, or *filtering*, is used.^{5,13} The purpose of the filtering process is to modify the ray sum data such that the back-projections consist of both positive and negative values. In the example of Figure 1-21, the profile of the back-projected density is modified to look like the one in *B* rather than that in *A*. The result is the cancellation of some of the back-projected densities of other ray sums and removal of the unsharpness.

The filtering procedure involves a mathematical operation on the ray sum with a "filter function" or convolution "kernel." The filter function is a complex one that depends on many parameters, including x-ray tube geometry and

Figure 1-19. Ray projections. *A*, The projection includes only voxels parallel to the matrix representation, and entire voxels are covered. *B*, The projection is oblique to the matrix. A weighting factor must be included for the back-projections to avoid giving these pixels undue influence.

Figure 1-20. Reconstruction by back-projection of a high-density object in diffuse media. Back-projection with 18 views (A), 36 views (B), and 72 views (C). Notice improvement of the image but persistence of star patterns with an increasing number of views. (Courtesy of Michael Menett, Technicare Corporation, and George Kambic, Marconi Medical Systems.)

detectors. It can take on a number of forms, depending on the desired result.^{3, 10} For example, one form of the filter function might enhance edges and thus sharpen the image, whereas another would blur edges for more gradual density changes. The edge-sharpening filter enhances spatial resolution but simultaneously decreases density resolution.

Thus, the choice of filter or kernel affects image quality, and the radiologist should be able to choose the best filter for a particular study. Some manufacturers automatically select the filters for particular procedures instead of requiring the radiologist to choose. Figure 1-22 illustrates the difference in applying various filter functions to the same data.

Image Reconstruction for Spiral CT

As described earlier, spiral scan data are acquired as the patient is moved continuously through the scan field by the table. If the data over a 360-degree rotation of the scan frame were reconstructed as in conventional (axial) CT, motion artifacts attributable to the movement of the table or patient would be visible.³⁰

To minimize these artifacts and to reconstruct a planar image anywhere throughout the volume of collected data, some data must be synthesized or interpolated. The simplest form of interpolation is *linear*. Prior to reconstruction, projection data are weighted to produce individual sections of data at select locations. Spiral interpolators apply

weighting factors to segments of the spiral data to estimate the data that would have been measured if an axial scan had occurred at a particular location.

Two common spiral linear interpolators are shown in Figure 1-23. A 360-degree interpolator uses two sets of spiral projections 360 degrees apart. This method assumes that projection data 360 degrees apart would be the exactly the same without patient motion. A 180-degree interpolator assumes that two measurements along the same path but in opposite directions would be the same without patient motion or other errors.

Generally, the more scan data that are used to reconstruct each image, the less noise, the wider the slice profile, and the longer the temporal resolution of the resulting image. Ultimately, the requested slice thickness, pitch, and spiral interpolator used for reconstruction affect the resulting z-axis resolution of spiral scan data.

As mentioned earlier, multislice CT complicates the fan-beam reconstruction techniques used by conventional and spiral CT by adding a divergence of the fan beam along the longitudinal axis (z-axis), creating a cone shape (cone beam) (see Fig. 1-17).

If the number of rows of detectors is limited to a small number (e.g., four rows), the cone-beam divergence is very small relative to the resolution of the detector element. This greatly simplifies the reconstruction of multislice data follows; just as in single-ring spiral reconstruction, only the alignment of projection rays as they cross the z-axis needs to be considered in the interpolation process. In

Figure 1-21. Effect of filtering in the back-projection method. *A*, Technique without filtering. *B*, Technique with filtering. The back-projected ray now has an area of decreased intensity directly adjacent to it, as shown by the profile of the back-projected ray optical density. When many projections are used, the negative aspects of the back-projections tend to smooth the image. *C-E*, Effects of performing the filtration function on the images of Figure 1-20 with 18, 36, and 72 views, respectively.

Figure 1-22. Filter effects on CT images. *A*, Image with high-frequency filter. Note the sharp image appearance and enhanced edge detail. *B*, Image with low-frequency (smoothing) filter. Note the blurry effects and decreased image sharpness. This filter increases density resolution at the expense of spatial resolution. (*A* and *B*, Courtesy of Marconi Medical Systems.)

Figure 1-23. Algorithms showing 360- and 180-degree linear spiral interpolation. The 360-degree interpolator weights spiral data over two revolutions of the gantry, and the 180-degree interpolator weights spiral data over one revolution of the gantry.

the case of multislice interpolation, projection rays—either from neighboring detector rows or from rays 180 degrees apart (or more)—may be included in the interpolation.³⁷

One interpolation method (spatially invariant) is described as follows:

1. For a scan with a quad-pitch factor of 0.625, up to four rays in the neighborhood of the target slice position are weighted by an interpolation function (designed to extend over the width of two detectors), synthesizing projections for the reconstructed slice.
2. For quad-pitch factors less than 1, this weighting function consistently generates slices with an effective slice width that is 30% broader than the width of one detector.
3. For quad-pitch factors greater than 1, reconstructions are generated from projections synthesized by interpolating only two neighboring projections, again resulting in an effective slice width 30% broader than the width of one detector.

This approach to multislice reconstruction maintains a more uniform resolution for different pitch factors, allowing the user to simply choose smaller pitches for higher effective milliamperage and lower spiral artifacts and larger pitches for maximum patient coverage.

Other multislice reconstruction techniques are available where the interleaving of data is best suited at optimal pitches only.³⁷ For example, using a linear interpolator at quad-pitch 1.5 (or pitch 6) creates slice-profile broadening of nearly 30%, whereas a quad-pitch of 0.75 (or pitch 3) creates little broadening.³⁷ Quad-pitches of 0.5 (2), 1 (4), 1.5 (6) and 2 (8) compare in z-axis sampling to single-ring spiral scanning with a pitch of 2.

Display

Image display includes all of the system components necessary to convert the digital data provided by the reconstruction system to electrical signals used by the CT display monitor (cathode ray tube) or flat panel (liquid crystal display), enabling a graphic display of individual CT numbers representing attenuation values of individual sections of anatomy. In addition, the display system includes the ability to display patient information, scan protocol, and reconstruction parameters, and it provides the user many graphic aids to assist in the interpretation of clinical images.

CT Number Scale

After a CT scanner reconstructs an image, the relative pixel values represent the relative linear attenuation coefficients because the process of reconstruction is not conducive to the calculation of the absolute values of the attenuation coefficients. However, it is valuable to quantify the pixel value so that the physician can compare the composition of one tissue with that of another. A CT numbering system that relates a CT number to the linear attenuation coefficients of x rays has been devised and is given by

$$\text{CT number} = \frac{K(\mu - \mu_w)}{\mu_w} \quad (11)$$

where

μ_w equals the attenuation coefficient of water

μ is the attenuation coefficient of the pixel in question

Although the original EMI CT scanner (Electronics Music Industries, Ltd.) used a value of $K = 500$, the value of K now used on all CT scanners is 1000. In honor of Godfrey Hounsfield, the inventor of CT scanning,¹⁴ a CT unit is called a *Hounsfield unit* (HU). When HUs are used, air has a value of -1000 ; water, 0; and dense bone, $+1000$.

In theory, it is immaterial which value of K is used to construct a CT number scale as long as it can accommodate the accuracy of the scanner. For example, if the density resolution of the scanner is $\pm 0.5\%$, the relative accuracy for density resolution is 1 part in 200 and a scale of 200 ($K = 200$) or greater is needed to depict the density resolution accurately. Using a value of $K = 1000$ expands the scale even more, representing a resolution of 1 part in 2000, or $\pm 0.1\%$. Magnifying the scale does not improve the accuracy of a scanner; for example, an accuracy of $\pm 0.5\%$ translates to ± 2.5 CT numbers with a scale of 500 and to ± 5 CT numbers with a scale of 1000.

As a general rule, the human eye cannot appreciate contrast differences of less than about 10%, whereas CT scanners can easily demonstrate differences of less than 1%. Thus, the small density-resolution difference measured by the CT scanner must be exaggerated to permit viewing. This is accomplished by enabling the user to select a small range of gray levels from the entire CT number scale and to reset the black and white limits.

For example, the CT numbers of liver tissues lie approximately in the range of 40 to 90 HU on a Hounsfield scale of 1000. If a portion of the scale with a CT number equal to 40 HU or lower is set at black and a CT number equal to 90 HU or greater is set at white, the scale of visualization is 50 HU and the entire range of liver tissues covers a contrast range of 100%. Now a density change of 10 HU on the original scale, which represents a true 1% contrast change, is converted to a 20% (10/50) contrast change on the adjusted range. This provides a large increase in visual contrast.

The range of CT numbers selected for gray scale ampli-

fication is called the *window width* and can generally be selected in scanners from 1 to full scale. (At the setting of 1, all pixels are either black or white.) The position describing the center of the scale is called the *window level*. Figure 1-24 shows a liver scan with different window settings. In this example, one can see the importance of the interactive display and the choice of settings by noting that in wide windows liver metastases are not well visualized.

Other display features and graphic aids assist the user in the interpretation of clinical images beyond window width and level control. For example, users have the ability to select a region of interest (ROI). Magnification of the image within the region of interest for better viewing is called *zoom reconstruction*. Some systems merely expand the image in the region of interest by expanding the pixel size on the viewing screen. This does not improve the accuracy of the scan but does allow possible visualization of some smaller structures because of better optical perception. Other systems increase image size but reconstruct the image with a smaller pixel size. This maneuver not only improves visualization of structures, because of optical reasons, but also increases spatial resolution if the pixel size is not smaller than the inherent resolution of the data (Fig. 1-25) (see "Matrix Size").

The region of interest is also used to acquire more information about pixel statistics, such as values of CT numbers in individual pixels, the average value in a number of pixels, or the number of pixels in a particular circumscribed region.

Several other display features are common to most device manufacturers, including the ability to pan and zoom images, scroll images, or view images in a cine mode. Image orientation can be inverted left to right or up and down. User-defined scales, straight or curved, may be placed anywhere on images. Finally, alphanumeric annotations may be placed anywhere on the displayed image to be filmed at a later time.

Advanced Display

Multiplanar Reformatting

Because a conventional CT study consists of several contiguous axial images perpendicular to the long axis of the body (see Fig. 1-1), coronal or sagittal images are not possible except when the gantry is tilted or the body is positioned to show the image in the desired plane. This limitation of CT can be overcome by image manipulation commonly referred to as *multiplanar reformatting* (MPR).

In this process, image data are taken from several axial slices and are reformatted to form images. In this viewing mode, the user defines the number of imaging planes, their position, orientation, thickness, and spacing, and the reformatted image is displayed in sagittal, coronal, or oblique planes. In the x-y plane direction, the pixel of the reformatted image has the same length as the axial image; in the z-direction, however, the pixel length is the same as the slice thickness. Since in most scans the pixel length is considerably smaller than the slice thickness, the reformatted scan can have an unusual appearance (Fig. 1-26). The resolution is quite good in one direction but very poor in another. This problem can be improved by scanning at a small-slice thickness and, as described earlier, the image is best enhanced with the use of spiral/multislice CT scan-

ning, in which longitudinal resolution permits a slice thickness resembling minimal pixel length in the x-y plane. Scanning in this mode is commonly referred to as *isotropic imaging*. Isotropic voxels permit increased visualization of anatomy of complex shapes that do not run linearly along the z-axis (patient axis).

Multiplanar Reconstruction Viewing Mode for Interventional Procedure Guidance

With the use of spiral CT data, an interactive viewing mode consisting of axial and MPR views, as just described, can be employed in conjunction with an articulated arm to create a planning tool for image-guided CT interventional procedures. The arm is mounted on the CT gantry and is calibrated to the CT scanner's coordinate system, including integrated movement of the patient table. As an interventionist moves the arm's needle guide along the patient's skin, axial and MPR images are displayed, representing the needle guide position, trajectory, and depth of a virtual needle path in correlation with the interventional field. Correlation between actual needle placement and the virtual needle path in this method is within a radius of 2 mm (Fig. 1-27A and B).

Figure 1-26. C-spine CT image. *A*, Multiplanar reformatted images acquired with a slice thickness of 2.5 mm depicting stair-stepping artifacts. *B* and *C*, Multiplanar reformat of images acquired with a slice thickness of 0.5 mm (isotropic resolution). The reduction in stair-stepping artifacts is due to the enhanced z-axis resolution of the originally acquired spiral data set. (MX8000 multislice CT images courtesy of Dr. Jay Cinnamon.)

Figure 1-27. *A*, PinPoint five-point articulating arm and needle guide demonstrating relationship of arm to gantry. *B*, PinPoint multiplanar reconstruction (MPR) views used to visualize a virtual needle path to plan interventional procedures.

Data from successive slices can also be reformatted to generate other viewing modes. Three-dimensional *shaded surface*, *volume rendering*, and *maximum intensity projection* (MIP) are a few examples. Each of these rendering techniques is described in detail.

Figure 1-28A illustrates a small segment of eight voxels representing a large volume data set for demonstration purposes. Each of the eight voxels is shown with their values displayed. A *viewpoint* is defined from where imaginary rays are projected. To simplify the example, we can assume that each ray intersects two voxels, one behind the other.

Three-Dimensional Shaded Surface

For a surface rendition, the user selects a threshold range (Fig. 1-28B). This allows the user to select only the tissue (e.g., bone) to be rendered. The voxels with Hounsfield values within the threshold range are set to the "on" state, whereas the rest of the voxels are set to the "off" state. Depending on the number of bits used for display, "on" and "off" voxels are assigned appropriate values. For an 8-bit display, "on" would be 256 and "off" would be 0.

The second step is to project rays through the entire volume. As the rays pass through the data, they stop when they identify the first "on" voxel. For that particular ray, this first "on" voxel is part of the surface; the other voxels are ignored. This is done for all the rays, and all the "on" voxels are used to create the surface. For our example, the "on" voxels that are part of the surface would be yellow in Figure 1-29C. As the name suggests, only a surface is displayed in this method; there are no details within the surface. Shading the voxels enhances the effect, so that the volume image appears to be illuminated by light sources. Multiple light sources can be used, but a single light source is used in most medical applications.

Three-Dimensional Depth-Based Shading

One type of shading technique is called *depth-based shading*. With this method, those voxels that are closer to the viewer are illuminated at a greater intensity than those that are farther back. As described earlier, it is also possible for the operator to select a range of CT numbers to display. If an operator were interested in a 3D view of the skull, he or she would select the range of CT numbers of the skull. The computer would then assemble those selected voxels

Figure 1-28. A, Sample of eight-voxel data set with displayed CT number values. B, User-defined threshold of CT number values for tissue definition. C, Shaded voxels represent defined tissue surface (shaded-surface display). (Courtesy of Shalabh Chandra, Marconi Medical Systems.)

C Gray voxels contribute to the 3D shaded surface

Figure 1-29. Sample of eight-voxel data set with representative opacity values assigned to various CT number ranges. (Courtesy of Shalabh Chandra, Marconi Medical Systems.)

Opacity values for the voxels is given by:

$HU < 50, \alpha = 0.0; 50 \leq HU < 200, \alpha = 0.2; 200 \leq HU, \alpha = 0.5$

into a 3D image. The result is a reconstructed 3D image of the skull with the soft tissue removed.

As with sagittal and coronal images, the quality of the image is improved by interpolating the data between slices to form a smooth, continuous image. When various 3D views are selected sequentially in time, the 3D image can appear to rotate. These images pose the same challenges as do sagittal and coronal images. The vertical resolution is the same as the slice thickness and not nearly as good as it is in other directions. Thus, spiral/multislice CT dramatically improves 3D viewing because of the inherent ability to cover the same anatomy as a conventional CT scanner at much thinner slice thicknesses and with overlapped image reconstructions.

Volume Rendering

Another possible viewing mode is *compositing/volume rendering* (VR). VR is an advanced rendering technique that displays an entire volume set with control of the opacity or translucency of selected tissue types. In this case, each voxel has an associated intensity in addition to an associated opacity value. Figure 1-29 shows the same 8-voxel block as Figure 1-28A, with each voxel having an opacity value associated with it. The user can define the opacity values for various HUs. Once the opacity values are assigned, the second step is to pass rays through the volume, accumulating values along the way. The formula for accumulating the values is given as

$$\text{final value} = I_1 \times \alpha_1 + I_2 \times \alpha_2 + \dots + I_n \times \alpha_n \quad (12)$$

where

$$\alpha_1 + \dots + \alpha_n \leq 1.0$$

I_n is the intensity of the voxel n

α_n is the opacity associated with the voxel n

n is the number of voxels added before the opacity values sum up to 1.0, or it is the total number of voxels along that ray for that data set

Using this formula along with the voxel intensity and opacity values shown in the example, one can calculate the final image. Figure 1-30 demonstrates the results.

The obvious advantage of VR over 3D shaded-surface rendering is that it provides volume information. By using transparency, the operator can visualize information beyond the surface. For example, VR is the preferred viewing mode for stent evaluation because stents can be made transparent to view the lumen of vessels. Other clinical examples include the ability to make plaque transparent for more accurate diagnosis of vessel stenosis.

Maximum Intensity Projection

Using *maximum* or *minimum intensity projection* (MIP) for visualization permits easy viewing of vascular structures or air-filled cavities. Compared with 3D or volume-rendering techniques, MIP is a relatively simple method. Unlike 3D shaded-surface and VR displays, no preprocessing is required. The rays are cast throughout the volume, and depending on whether it is maximum or minimum intensity projection, maximum or minimum values along the rays are used in the final image display. On the basis of the 8-voxel example described earlier, Figure 1-31A and B shows the final pixel values for maximum and minimum intensity projections.

MIP is a preferred method for many CT angiography applications, since visualization of contrast-filled vasculature is fast and easy. Maximum intensity projection enables easy viewing of an entire vessel in one image. This is true because voxels representing the contrast-filled vessels are most likely to be the ones with the highest values along the ray (assuming no bone along the ray). Along the same lines, minimum intensity projection can be used to demonstrate air-filled cavities.

Image Quality

Several quantitative measurements are used to define a CT system's image quality:

- Spatial resolution
- Contrast resolution
- Noise
- Slice sensitivity profile
- Temporal resolution
- Dose

Spatial Resolution

Spatial resolution is measured by the ability of a CT system to distinguish two small high-contrast objects located very close to each other under noise-free conditions. Optimal spatial resolution is required for evaluating high-contrast areas of anatomy, such as the inner ear, orbits, sinuses, and bone in general because of their complicated shapes.

Spatial resolution can be specified by spatial frequencies, which indicate how efficiently the CT scanner represents different frequencies. *Modulation transfer function* (MTF) describes this property. A 2D *Fourier transform* of the point spread function, taken with a very thin wire, provides MTF values. These concepts will be described shortly.

Consider the image of a point source that can be obtained by placing a thin wire on end in water or plastic and then scanning across the wire. Ideally, the resulting image should be a uniform background with a bright dot denoting the position of the wire. In fact, the image does demonstrate the bright dot but with a fading periphery rather than an absolutely sharp edge.

A profile across the image (i.e., a plot of the picture density along a line passing through the point source center) produces a bell-shaped distribution, called the *point response distribution*. The height of this curve represents the maximum value of the density, and the width represents the uncertainty in the measurement of the exact boundaries of the wire.

Full width at half-maximum (FWHM) is the width of the curve at the point where the attenuation values are 50% of the peak value (Fig. 1-32). The smaller the FWHM, the better the resolution. One can appreciate this fact by noting that a large FWHM reflects a larger fading periphery, which means a poorer reproduction of the actual object.

Another method of examining spatial resolution is to consider line images. This is similar to examining point images; however, the scan would be done parallel to a wire in a medium rather than across the axis. If a series of lines of different spacing or of different sizes were used, the ability to distinguish separate lines in an image would measure the spatial resolution.

With very fine lines, a measure of the resolution can be stated in terms of the number of lines that are still discernible, packed together in a given distance. Thus, one would speak of the number of lines per centimeter that could be visualized in the image. Describing the spatial resolution in terms of lines per centimeter is said to describe the resolution in the frequency domain. The frequency, in this case, is the parameter, lines per centimeter. A profile across the line image yields the *line response curve*, which is similar to the *point response curve*. Again, one can speak of FWHM, and the analysis is similar to that done with the point source. Obviously, the two response curves are related.

Performing a mathematical operation, the Fourier transform, on these response curves yields the MTF.^{7, 19} The physical interpretation of the MTF is that it displays the relative fidelity of the image compared with the actual object.

Another description of MTF is shown in Figure 1-33. The rectangular profile represents the density profile of an object composed of dense lines. The density profile of the reconstructed image is shown as rectangles with rounded corners.

As the lines become closer together, the region between lines fills in because of the overlap of the response functions. The ratio of the height of the rectangles to the height

Figure 1-32. Definition of full width at half-maximum (FWHM). A, Solid body in uniform media. B, Profile across the image demonstrates the fading periphery of the image of the body. The rectangular curve represents the ideal response with sharp edges.

of the valley between lines becomes smaller as the lines become closer in the reconstructed image but, obviously, is fixed in the object. This change, or decrease, in ratio is seen as a decrease in contrast and is a manifestation of the decreasing ability of the system to resolve small objects (or small separation of objects). The MTF is basically the value of this ratio in the image divided by the value of the ratio in the object. As the frequency increases (i.e., more lines per centimeter), the ability of the system to reproduce the lines and valleys accurately is decreased and the fidelity also therefore decreases.

With widely separated lines, the MTF is 1—the maximum value; as the frequency increases, the MTF drops. Thus, the higher the MTF at a given frequency, the better the fidelity (i.e., the better the resolution).

In systems with large values of MTF at high frequencies, edges are more clearly defined; such systems produce images that appear sharp. If high frequencies are exaggerated relative to low frequencies, the result is an edge enhancement. Techniques for such high-frequency enhancement are often used to advantage in radiology, and this is the main purpose of xeroradiographic methods or

subtraction methods. In Figure 1-34, curve A denotes a system with an MTF better than that shown by curve B; in this case, system A would have better resolution than system B.

The spatial resolution (composite MTF) is affected by many design parameters. The most important are as follows:

- Choice of filter used in reconstruction
- Opening size of detector aperture
- Number of projection profiles obtained
- Matrix (or pixel) size
- Focal spot size of the x-ray tube
- Relative object-to-background contrast (density)

The last two parameters in this listing are presented after the topic “Contrast/Density Resolution and Image Noise” (see later). Samples (rays and view or number of detectors), and not other parameters, gate the composite MTF for most third-generation systems. Focal spot size or detector aperture size typically gates the composite MTF of fourth-generation systems.

Filter Effects on Resolution

As discussed earlier, the major role of the convolution filter is to remove the image blurring created by the back-

Figure 1-33. Definition of modulation transfer function (MTF). As the line frequency increases, the relative image contrast decreases, which is reflected in the fall of the MTF.

Figure 1-34. Comparison of modulation transfer function (MTF) of two theoretical systems. The system represented by A demonstrates a better spatial resolution than that of B.

projection process. Various filters control the amount of image blurring created by accentuating high-frequency components found in the data. For a crisp image, the high spatial frequencies are accentuated, and this has the effect of sharpening the edges and improving resolution. If the high spatial frequencies are not accentuated, the image of the object appears more blurred.

A tradeoff is that image noise increases and the density resolution diminishes with accentuation of high spatial frequencies. One pays for a crisp picture with a decrease in density resolution. Similarly, by increasing density resolution, one pays by loss of some spatial resolution and image crispness.

Opening Size of Detector Aperture

The detector aperture MTF curve is dependent on the magnification factor of the system (focal spot to detector distance/focal spot to object distance) and the physical size of the detector.

Consider the rotate-only scanner (Fig. 1-35). As the system rotates, the ray projection for a particular detector acts as the cord of the circle rotating about the center at a distance, R . The aperture opening for a particular detector, therefore, is associated with a particular data ring about the center. It is clear from the diagram that as the aperture size increases or decreases, the width of the data ring increases or decreases correspondingly. The width of this data ring characterizes the attenuation profile and is crucial to the spatial resolution. For example, if the object being viewed is smaller than the width of the data ring, it will be difficult to resolve because it occupies only a fraction of the space seen by the detector.

Typical detector apertures of CT systems today range from less than 1 mm to 1.5 mm, with center-to-center detector spacing of approximately 1 mm.

Number of Projection Profiles

As stated previously, to obtain a solution for the image reconstruction, Equation 10 must be obtained for each

value of λ needed. Therefore, if one wishes to reconstruct an image with a matrix of n columns by n rows, then n^2 measurements or ray sums must be obtained. With the large number of detectors used in present machines, this criterion is easily met. Although this criterion is necessary, it is not sufficient to guarantee the requisite resolution, and the question of optimum number of angular measurements or views must be answered.

Review Figure 1-35, and note that the resolution depends not only on the thickness of the data ring but also on the arc length of the data ring section between radiation measurements. Theoretically, this optimum number depends on required resolution and object size.^{18, 26} To obtain resolution of 1 mm with small or average-sized bodies, 300 to 400 views may suffice; for larger bodies, 700 to 800 views may be needed. All current instruments of both the stationary detector type and rotate-only type have the capability of meeting these requirements. In many machines, these needs are exceeded significantly, allowing spatial resolution down to the range of 0.25 mm.

Matrix Size

It is rather obvious that the spatial resolution can be no better than the size represented by the pixel length. In reality pixel size should be $1\frac{1}{2}$ to 2 times smaller than the desired resolution. Unless a matrix element exactly coincides with an object, the object representation will be averaged over two or more pixels and thus may not be visualized. It must be realized that the pixel size refers to the FOV (or body), not the viewing screen or film. For example, in a field size of 50 cm in diameter, a matrix size of 512×512 would indicate that each pixel represents a 0.98×0.98 mm area in the FOV:

$$\text{pixel size (mm)} = \frac{\text{FOV (500 mm)}}{\text{matrix (512)}} \quad (13)$$

Typical matrix sizes available in scanners today are 512×512 and 1024×1024 . Most CT scanner display systems include zoom factors. If a zoom factor is used, the formula for pixel size must be modified to reflect the decreased FOV as follows:

$$\text{pixel size} = \frac{\text{scan FOV}}{\text{matrix} \times \text{zoom}} \quad (14)$$

The imaging goal is to match the pixel size with the inherent resolution of the CT system and scan protocol/filter selection for each examination. As discussed earlier, spatial resolution is measured in line pairs per centimeter. To convert this to millimeters, use the following formula:

$$\text{spatial resolution (mm)} = \frac{10}{2} \times \frac{\text{lp}}{\text{cm}} \quad (15)$$

To illustrate the concept, consider a high-resolution study with a protocol and reconstruction filter designed to achieve a spatial resolution of 20 lp/cm and an FOV of 250 mm. Converting 20 lp/cm to spatial resolution in millimeters using the preceding formula results in 0.25 mm spatial resolution.

Figure 1-35. Single-ring, third-generation detector aperture. The thickness of the ring depends on the aperture opening.

To achieve a pixel size of 0.25 mm without zooming, the reconstructed FOV requires a matrix of 1024×1024 ($250 \text{ mm}/0.25 = 1000$). To use a matrix of less than 1024×1024 would suggest a visual loss of spatial detail. The data are available but cannot be viewed.

Spiral and Multislice Spiral CT Effects on Spatial Resolution

Factors that affect in-plane spatial resolution for spiral and multislice spiral CT are the same as for conventional CT, although spatial resolution greater than 10 lp/cm (see third-generation CT earlier) is limited to axial modes of scanning or to manufacturers who employ special x-ray tube focal spot techniques to increase the data sampling rate during spiral scanning.

Unlike *in-plane* resolution, reconstruction in this chapter refers to a potential loss of z-dimension (*through-plane*) spatial resolution (for a given slice width) during spiral or multislice spiral CT. The loss of resolution, as measured at the FWHM of the slice sensitivity profile, is dependent on the spiral interpolation algorithm used during reconstruction and, in some cases, the pitch factor used. This phenomenon is less relevant for multislice spiral CT. This is evidenced by the fundamental clinical benefit of multislice spiral CT in covering more anatomy with thinner slices (better z-axis spatial resolution) compared with the benefits of conventional spiral CT.

The issue of degraded slice sensitivity profiles based on interpolating techniques in this case is fairly moot. For example, a best-case, single breath-hold examination, completed with the use of single-ring spiral CT at a given dose and level of image quality, may require a slice thickness of 5 mm. This same examination can be completed in less time with a slice thickness of 2.5 mm using multislice spiral CT.

Whether the slice sensitivity profile at FWHM broadens to 2.8 mm or to 3.2 mm becomes irrelevant. However, radiologists should become familiar with the typical slice broadening associated with different protocols on the CT scanner in use at their practice. Some manufacturers report the actual slice thickness, whereas others report only the requested slice thickness. It is important for radiologists to know the difference because the slice sensitivity profile indicates the CT scanner's ability to image objects within a given slice thickness. If the actual slice thickness is larger than expected, partial-volume averaging may affect the axial image quality. In addition, MPR reconstruction may be moderately affected.

Contrast/Density Resolution and Image Noise

The second major factor affecting the ability of a scanner to accurately describe anatomy is contrast, or density resolution, or the ability to differentiate the attenuation coefficients of adjacent areas of tissue. Because most soft tissues have densities that are very nearly the same, usually the differentiation of variations of a few percent or less are considered. In the computation of any single pixel value,

there is error in the form of statistical variation; it is this variation that limits the ultimate contrast resolution. This variation (called image noise) is manifested as a grainy background, or mottle. The parameter used to evaluate this variation is the standard deviation (SD, or σ), and the usual procedure for evaluating a system is to obtain a scan of a uniform substance, such as water, and to compute the SD by the following formula:

$$SD = \sigma = \sqrt{\frac{\sum_{i=1}^n (CT_i - \overline{CT})^2}{n - 1}} \quad (16)$$

$$\overline{CT} = \frac{1}{n} (CT_1 + CT_2 + \dots + CT_n) \quad (17)$$

where

n is the number of pixels used in the evaluation

\overline{CT} is the average pixel value for n pixels

CT_i represents individual pixel values

The meaning of the SD is that rescanning of the same water bath and a recalculation of the same pixel CT numbers would yield values in a range equal to the previously calculated value \pm SD in approximately two out of three instances. The SD, therefore, describes the uncertainty in a measurement and is commonly expressed in terms of percentages. This percentage is obtained by dividing the computed SD in CT units by the range of the scale.

For example, SD equal to 5 HU on a Hounsfield scale of +1000 would translate to $5 \text{ HU}/1000 \text{ HU} = 0.005$, or 0.5%. The interpretation is that two adjacent pixels are not significantly different if their CT numbers vary by 5 HU or less.

Since noise is the ultimate limitation in the accuracy of the density resolution, parameters that affect or induce noise need to be understood. The most important parameters are (1) photon flux, (2) x-ray scatter, (3) computation-induced error, (4) filter frequency response, and (5) voxel size. The effect of filters was discussed previously.

In any ray measurement, the statistical variation associated with that measurement is directly proportional to the number of photons detected. If I is the number of detected photons, the SD is given by the square root of I , and the relative noise in a ray measurement is given by

$$\frac{\sqrt{I}}{I}$$

which reduces to

$$\frac{1}{\sqrt{I}}$$

Because the variation in a ray measurement is propagated into every pixel computation, which involves the ray, the relative image noise is affected inversely as the square root of the detected photon flux. Large photon fluxes, or increases in milliamperes, as controlled by the radiologist, can reduce relative noise; unfortunately, they also increase radiation dose levels. Therefore, limits on CT image noise

reduction are imposed by practical limitations of increased dose to patients. The radiologist has an obligation to accept the highest noise image (lowest dose protocol) that is possible consistent with a definitive diagnosis.

The photon intensity that is detected, not the intensity impingement on the patient, must be taken into consideration, as mentioned previously. The efficiency of the detector, impinging photon flux, size of the patient, and presence of high-attenuation materials affect the detected intensity and, in turn, the uncertainty in the measurement. The image of a large patient thus has a more mottled appearance than the image of a small patient for the same tube output. Similarly, the presence of a high-contrast object, such as bone or a prosthesis, causes increased noise by reducing the transmitted photon flux.

Another aspect of noise is x-ray scatter. Because image-energy discrimination cannot be used in systems with the continuous energy spectrum obtained from an x-ray tube, no detector in particular can discriminate between a primary photon directly from the source and a scattered photon arising from an area not in the line of the ray projection. In the energy range used in scanners, many photons are scattered through small angles. The effect is to alter the recorded values in adjacent detectors. This produces a decrease in differences between adjacent measurements with a concomitant decrease in contrast resolution. The sharp interfaces between tissues also are diminished by this phenomenon, causing a reduction in spatial resolution.

The amount of scattering that is detected is controlled by collimation of the detectors. Smaller apertures reduce scattering and therefore reduce the noise component due to scattered photons. The measured intensity is also affected by the voxel length (i.e., slice thickness). If the slice thickness is reduced by 50%, the detector collimator size must be reduced accordingly, which in turn reduces the intensity by the same amount. To retain the same accuracy, one must restore the detected photon intensity, which means doubling the dose.

Similarly, decreasing pixel size increases the relative inaccuracy unless the photon flux is raised. If the pixel side

length is reduced by half, the voxel volume represented by the pixel is reduced by a factor of 4. The SD of the resulting calculated CT number, shown earlier to vary as the square root, would double. The image would become more mottled in appearance, and the contrast resolution would deteriorate. To restore the uncertainty to its previous value, one would need to increase the radiation dose by a factor of 4.

These relationships between the factors of slice thickness (h), pixel size (L), SD (σ), and radiation dose (D) are shown⁶ as

$$\sigma = \frac{C}{[DhL^2]^{1/2}} \quad (18)$$

where C is a constant.

This relationship also emphasizes that low contrast/density resolution (as reflected through the SD) is related to spatial resolution (as reflected through aperture opening or pixel size), and these two factors of image quality cannot be treated completely separately. Spatial resolution is usually stated for objects of high contrast. In CT scanning, attenuation coefficient differences of approximately 12% or greater are considered high contrast. As contrast differences decrease, spatial resolution also decreases. Figure 1-36 demonstrates the resolution obtained by viewing similar line phantoms but with various contrast differences.¹

For a given dose level, regardless of the size of the object, a minimum density resolution exists, and, regardless of dose or contrast, there is a minimum size that can be resolved. Changing the dose level alters the minimum density resolution but not the spatial resolution limits¹¹ (Fig. 1-37).

Spiral and Multislice Spiral CT Effects on Contrast Resolution and Image Noise

The same variables that affect image noise and contrast resolution for conventional CT—slice thickness, kilovolt-

Figure 1-36. Line phantom. A, High-contrast line pairs; note the clarity. The diameter of the pairs and center-to-center distances are 5, 3, 2, and 1 mm. B, The same phantom with low contrast difference between the lines and the surrounding media. Notice the relatively poor spatial resolution, compared with A, and the inability to visualize the finer lines. This demonstrates the relationship between contrast and spatial resolution. (From Bellon EM, Miraldi FD, Wiesen EJ: Performance of evaluation of computed tomography scanners using a phantom model. *Am J Roentgenol* 132:345-352, 1979. Copyright American Roentgen Ray Society, 1979.)

Figure 1-37. Interplay of spatial resolution, density resolution, and radiation dose. As the dose level increases, contrast resolution improves. High-contrast resolution is fixed and cannot be improved by the dose level. For a given dose level, objects with sizes and contrast that lie above the curve can be resolved; those below the curve cannot be resolved. (From CT/T Continuum: Evaluation Criteria. Milwaukee, General Electric Medical Systems, 1980.)

age, milliamperage, patient size, voxel size, and convolution filter—affect spiral and multislice spiral CT, with the added variables of table speed (pitch) and spiral interpolation algorithm. For a given pitch, using more scan data to reconstruct an image (with linear interpolation) reduces noise and enhances contrast resolution at the expense of z-axis spatial resolution.^{20, 29}

Temporal resolution refers to the ability of a CT scanner to capture objects that change shape or position over time and depends primarily on the gantry rotation speed and the reconstruction method used. For conventional CT using a full 360 degrees of scan data, temporal resolution is equivalent to scan time per rotation. A 1-second scan has a 1-second temporal resolution.

For spiral or multislice spiral CT, temporal resolution is dependent on the gantry rotation speed and the spiral interpolating algorithm used during reconstruction. Figure 1-38 depicts a 180-degree linear interpolator that demonstrates the relative spiral weighting values applied to projection data at the center of an axial slice. The central 180 degrees of data, including the fan angle (~50 to 55 degrees) are acquired in approximately 0.625 second for a gantry rotating at a speed of one revolution per second. The temporal resolution (FWHM) for a 360-degree linear interpolator, which uses 720 degrees of scan data, is approximately 1.25 seconds, or double that of the 180-degree interpolator.

A recent advancement that permits the reconstruction of projection data at prescribed intervals coincident with a patient's heart rate (electrocardiographic waveform) permits reconstruction techniques that can reduce effective temporal resolution to approximately 100 msec or less for data acquired using 0.5-second gantry rotation speeds. As described in Chapter 63, temporal resolution of this magnitude permits entirely new applications for CT such as cardiac and functional CT imaging.

Patient Radiation Dose

The amount of irradiation a patient receives during a CT examination is a function of many parameters. The dose can vary considerably from scanner to scanner and from image to image, depending on what is required by the radiologist (see preceding discussion). There are many methods of measuring and characterizing radiation delivered by CT.

Most methods use a standard cylindrical dosimetry phantom, with the dosimeters placed on the surface of and inside the phantom.^{1, 22, 25} Measurements made on this type of phantom should not be considered a precise measurement of patient dose. True patient dose is not very well simulated by a perfectly cylindrical plastic phantom because of such factors as positioning errors, variations in patient shape, and uncertain x-ray attenuation. However, these methods are useful in demonstrating how dose varies as a function of operating conditions and between scanners.

Figure 1-38. Weighting values of a 180-degree linear spiral interpolator demonstrating temporal resolution (full width at half-maximum) of approximately 0.625 second for a 1-second, 360-degree scan.

Most methods involve measuring the surface and internal doses for single slices and multiple, contiguous slices. There is a nonuniformity of absorbed dose distribution from different CT scanners because of various scanning conditions, system geometries, x-ray beam collimations, and filtration systems that make single-number dose descriptions, such as peak and average doses, inadequate.

Another concept suggested by Bureau of Radiological Health personnel to overcome some of these problems is the *computed tomography dose index* (CTDI).²⁵ To obtain the CTDI, a pencil-shaped ion chamber is inserted in a hole drilled in a plastic phantom. One single-slice measurement is taken. Because the ion chamber is long in relation to slice thickness, the ion chamber measures primary radiation as well as all scatter radiation. A single number that represents the average dose for a single scan is obtained. Holes may be placed at any depth along the axis of the phantom to measure the dose at any depth.

The *multiple scan average dose* (MSAD) represents the average dose delivered to a patient for a series of axial scans. This dose can be calculated by multiplying the ratio of the slice width to table index by the CTDI.

Values of skin dose can vary from a few tenths of 1 rad to high values above 15 rad and are controlled by the technique set by the operator. Depending on the x-ray beam primary energy, the amount of filtering in the beam, and the number of slices scanned, the patient internal dose may approach the skin dose for multiple slices.²⁵ Organs located outside the scanned volume will receive a dose because of scattered radiation from that volume and some leakage radiation from the x-ray tube housing. At distances of more than 1 cm from the scanned volume, the internal dose is relatively low.²²

From the previous sections and as related by Equation 18, the inclination is to improve image quality by increasing the dose. Obviously, the radiologist must exercise prudence to obtain the necessary clinical information at the lowest possible radiation levels. Several published studies^{16, 21, 27} have demonstrated that results of adequate clinical examinations can frequently be obtained with a great reduction in dose and with picture aesthetics as the only significant difference.

As described earlier, both spiral CT and multislice spiral CT generate axial/planar slices from a volume of data collected while the patient is continuously moved through the x-ray beam. As such, controlling the speed of table movement (pitch) can affect the average patient dose for the total examination.

As an example, consider a protocol with a slice width of 5 mm and a pitch of 5 mm, or pitch factor of 1:1. Extending the pitch factor from 1:1 to 2:1 by increasing the pitch to 10 mm effectively reduces the average patient dose in this examination by 50%. Conversely, reducing the pitch factor from 1:1 to 0.5:1 by slowing the pitch from 5 mm to 2.5 mm effectively increases the average dose by a factor of 2.

Multislice spiral CT complicates this equation somewhat, and z-axis dose efficiency must be considered. In this case, z-axis dose efficiency is defined as the ratio of the FWHM of the sensitivity profile to the FWHM of the radiation profile expressed as a percentage. For multislice systems, the FWHM of the sensitivity profile is the sum of the individual slices produced by that radiation profile. The

z-axis efficiency of multislice CTs varies by manufacturer but can be expected to approach 100% at slice thicknesses between 5 and 10 mm, gradually falling off in efficiency to approximately 75% at slice thicknesses of 1 mm. This falloff in efficiency is due to the penumbra-to-umbra ratio of the x-ray beam and is unique to multislice spiral CT. This is true because both the penumbra and umbra are detected with single-ring spiral CT systems but not true for today's multislice CT systems.

System geometry, x-ray tube focal spot length, and other collimation factors affect this ratio. In general, the wider the collimated beam, the smaller the penumbra-to-umbra ratio and, therefore, the lower the effect on z-axis efficiency. Manufacturers continue to develop new methods to improve z-axis efficiency with multislice spiral CT, and improvements are probable in the near term.

One final note: As the z-axis width of detectors increases from today's quad-slice systems to 8, 16, 32, 48 slices and beyond, z-axis efficiency will improve.

Image Artifacts and Their Causes

There are many causes of artifacts on an image, and it is important for the radiologist to recognize all types so that they can be eliminated or minimized.

Streak and Ring Artifacts

Streak and ring artifacts are usually the result of difficulty with the detector (Fig. 1-39A and B). With third-generation scanners, ring artifacts are seen if the x-ray detector is not properly calibrated.

In Figure 1-36, each detector is associated with a data ring. A malfunction of any one detector incorrectly back-projects along the data ring to produce the ring artifact. If a detector is not matched or is not intercalibrated accurately, the back-projection for each data ring would be slightly different, causing multiple rings. Poor alignment of tube and detector causes misplacement of calculated values, since measured values are occurring in lines different from those assumed by the reconstruction algorithm. The result can be blurring edges if the misalignment is slight or ring or streak artifact if the misalignment is great. Detectors in the center of the detector arc are most sensitive.

Fourth-generation scanners are more sensitive to streak artifacts due to failure of a detector. However, because of the large number of views available, data for the failed detector can be synthesized through interpolation.

Metal and Bone Artifacts

The presence of objects having an exceptionally high or low attenuation can create artifacts by forcing the detector to operate in a nonlinear response region. Because this incorrect response occurs at specific directions of the beam through the object, incomplete cancellation of the back-projected rays during reconstruction occurs and yields streaking artifacts. Metallic pins, for example, can give rise to streaks, as can gas (Fig. 1-40).

Figure 1-39. Examples of CT image artifacts. *A*, Ring artifact obtained with a third-generation CT scanner. *B*, Streak artifacts.

The range of x-ray intensity values to which the scanner can accurately respond linearly is called the *dynamic range*. The larger the dynamic range, the less prone the instrument is to creating such artifacts. In most new scanners, the dynamic range is a factor of 1 million to 1, which greatly reduces the metallic artifact problem.¹²

Beam-Hardening Artifacts

Beam-hardening artifacts result from the preferential absorption of low-energy photons from the beam. In the

range of kilovoltage used in CT scanners, a prominent mode of interaction is the photoelectric process, and in this region the low-energy photons are preferentially absorbed. Thus, as a beam traverses the body, the average beam photon energy is progressively increased. Accordingly, toward the end of the x-ray path, the attenuation is less than at the beginning because the attenuation coefficient is smaller with higher energy. The reconstruction program, however, assumes a monochromatic beam and attributes any change in beam intensity to a change in tissue composition rather than to the result of a shift in average photon

Figure 1-40. Streak artifacts. *A*, Uniform media with metallic pin; note the large amount of streak artifact. *B*, A hip prosthesis. *C*, Starburst streaks from clips in the pulsating heart of conventional (single-ring) CT scanner.

energy. The assigned attenuation coefficients are thus in error, and the densities seen on the image are in error. The effect is most pronounced in regions of large attenuation, such as bone.

The artifact is seen as a shadow beneath the ribs, for example, or increased shadows in the mediastinum or skull (Fig. 1-41*A* and *B*). This effect occurs throughout the image, but qualitatively it is not usually perceived except where there is a great deal of hardening (e.g., in the vicinity of bone). This effect can be compensated for by use of a correction method that consists of forward-projecting only the “bone” portion of an image and by determining the required correction via a polynomial.³⁶

Partial-Volume Artifacts

When tissues of widely varying absorption properties occupy the same voxel, the beam attenuation is proportional to the average value of the attenuation coefficient of the voxel. A volume average is computed for such voxels, leading to the partial-volume error. A common site of such an effect is the lung-diaphragm interface, where an increased density may be attributed to the lung base when, in reality, it does not exist (Fig. 1-42). A partial-volume artifact can be subtle and gradual, requiring care in interpretation. Another common partial-volume artifact is observed in scans of the head in the posterior fossa region.³¹

Motion Artifacts

A motion-induced artifact is usually streak or starburst in appearance and occurs where there are high-density or low-density interfaces (e.g., gas in the bowel) (Fig. 1-43). This occurs because movement during the measurement process causes structures to be in different positions when

different views are taken so the back-projections are not added correctly. Artifacts can also appear as “double imaging,” with the same outline shown twice.

Stair-Stepping Artifacts

Stair-stepping artifacts (see earlier) occur when in one direction the pixel of the reformatted image has the same length as the axial image but in the other direction the pixel length is the same as the slice thickness. Because pixel length in most scans is considerably smaller than slice thickness, the reformatted scan has an unusual appearance (see Fig. 1-26).

Spiral Pitch Artifacts

Pitch artifacts appear primarily because larger pitch factors are used to attain maximum coverage. Spiral artifacts exhibit similar stepping as axial scans in reformatted images, except that the steps appear as a spiral groove (Fig. 1-44).

Multislice pitch artifacts (again for large pitch factors) have a unique appearance in axial scans; a star pattern is seen off of sharp edges, where the number of spokes in the star is directly related to the number of multislice detector rows (Fig. 1-45).^{35, 37} This is because each row contributes only a portion of its projection data to the multislice reconstruction.

Cone-Beam Artifacts

As the number of rows in a multislice scanner increases, the divergence of the cone beam along the z-axis becomes significant relative to the detector width. For a small num-

Figure 1-42. Liver scan representing enhanced lesion detection and reduced partial-volume artifacts in A (2.5-mm slice thickness) versus B (10-mm slice thickness). (Multislice CT image courtesy of Dr. John Haaga.)

ber of rows, this effect is small and noticeable only for sharp objects distant from the scan center. For scanners with eight or more rows, the cone-beam effect becomes more significant, requiring the reconstruction process to account for the divergence effect (Fig. 1-46).

Summary

The tradeoff between spatial resolution (x-y), contrast resolution, and patient dose has been optimized for CT since the early 1980s. To obtain more low-contrast resolution for a given spatial resolution, the patient dose must increase. To obtain more contrast resolution while maintaining patient dose, spatial resolution must decrease. In short, before the late 1980s, the fundamental laws of physics prevented significant improvements in 2D CT imaging without increasing patient dose. The advent of spiral and

multislice spiral CT has not changed these limiting factors; however, by permitting radical improvements in z-axis spatial resolution, multislice CT enhances CT imaging of submillimeter anatomic and pathologic structures. Subsecond scanning techniques with rapid-volume coverage are enabling new functional imaging methods using CT. Finally, rapid developments of computer technology are enabling radiologists to take advantage of new 3D and 4D imaging methods, moving CT from a 2D anatomy-only tool to a 3D tool that can provide functional as well as anatomic information.

Many more clinical applications are on the horizon; this is just the beginning of a very promising future for CT as perhaps the most cost-effective, value-driven diagnostic imaging tool. Examples of many of the new CT clinical applications are described in the upcoming chapter on multislice spiral CT and are represented throughout this book.

Magnetic Resonance Physics: An Introduction

Errol M. Bellon, Pedro J. Diaz,
Jeffrey L. Duerk

The magnetic resonance imaging (MRI) study, as seen on a computer screen or on hard-copy film, is a translation, into visual format, of numerical values residing in a computer memory. The $N \times M$ numerical values that make up the image are referred to as *pixels* (picture elements). These values are generated from MRI signals acquired during scanning in a computational process known as *Fourier transform*. Thus, MRI represents a form of computed imaging, with the numerical value of the pixel represented on the screen as a level of gray using a digital-to-analog conversion process.

The intensity of the displayed pixel is proportional to its numerical value and reflects the cumulative strength of the radiofrequency (RF) signal received from a corresponding volume element (*voxel*) within the slice of tissue examined. This RF signal is dependent on these factors:

- Strength of the magnetic field
- Size and location of the RF detector (antenna, coil, surface coil)
- Relaxation parameters (T1 and T2) of the tissue
- Amount of mobile protons in the tissue (its proton density)
- Parameters of the MRI acquisition

In an MRI experiment, or scan, the patient is placed in the external magnetic field of the MRI magnet. The magnetic dipole moment of hydrogen nuclei in the body, which are normally oriented randomly in the weak magnetic field of the earth, are affected by this much stronger external field and undergo a net alignment parallel to the field. For example, a 1.5 Tesla (T) MRI system has a magnetic field approximately 30,000 times stronger than that of the earth in most of the United States. At this field strength, only about 2 to 4 in every 2 million protons from the patient contributes to the MRI signal; all others are canceled by protons pointing in the opposite direction.

Individually, the proton magnetic moments precess about the static field, but they can be evaluated collectively such that the net magnetization is initially pointed along the static field. When subjected to brief periods of RF energy, the hydrogen nuclei in the patient's tissues absorb the RF energy and alter their orientation. In this new alignment, the net magnetization can be shown to precess about the static field. The absorbed RF energy and subse-

quent precession and realignment of the nuclei allow them to function as miniature RF transmitters as they return to their previous parallel alignment. Their RF signal is measured (received) by means of an external RF antenna (*coil*).

Repetitive systematic variations in the strength of a second magnetic field (generated by gradient coils inside the magnet) during the time the nuclei are stimulated by the external RF signal makes it possible to selectively excite individual areas of the body. Recording and subsequent processing of these spatially localized data result in the clinical MRI scan.

A detailed discussion of the underlying physics of MRI is beyond the scope of this chapter. Hence, an overview of the concepts and most common technologies that are part of the process of MRI generation is presented in this chapter.

Nuclear Spin, Magnetism, and Magnets

Atomic nuclei have a property called *nuclear spin*. Nuclei, which possess an odd number of individual neutrons, protons, or both, have a net spinning charge. For the hydrogen nucleus, which consists of a solitary proton, its single moving electrical charge creates a tiny magnetic field. This magnetic field is analogous to that generated by current flowing in a wire loop, and it behaves like a small bar magnet (or magnetic *dipole*) oriented along the spin axis of the nucleus (Fig. 2-1). These magnetic dipoles, in the absence of external influences, are oriented randomly and, as such, have zero net magnetization (Fig. 2-2). In the presence of an external field, the laws governing the rotation of this spinning nucleus are analogous to those governing a spinning top. The spinning top, because of its mass and moment of inertia, precesses about the earth's gravitational field. The nucleus, because of its magnetic dipole field, precesses about the external magnetic field (Fig. 2-3).

When a hydrogen proton is placed within a magnetic field, the dipole aligns itself with the field in one of two ways: either in the direction of the field (*parallel*) or opposite to the field (*antiparallel*). These orientations correspond to lower-energy and higher-energy states of the

Figure 2-1. Representation of magnetic properties of the proton. The equivalent bar magnet arises as a result of nuclear spin about the axis (dotted line). The introduction of an external magnetic field (B_0) causes the bar magnet to precess about its axis (solid line).

dipole, respectively. By analogy, consider the task of aligning a spinning top that can be secured only at its tip, with the gravitational field of the earth. In one case, if one is very careful, the top is pointed up even though gravity is trying to pull the top over. If the top is secured at its tip, it is more likely that the top would hang down, along the gravitational field. Clearly, the top that is aligned with the gravitational field is in a lower-energy state and hence is more probable to occur in exactly the same way that the proton aligned with the magnetic field is in a lower-energy state and hence more likely to occur. The magnetic dipole of the proton is thus oriented anywhere around the surface of either one of two cones (prescribed by the precessing dipole), depending on whether the nucleus is in a parallel or antiparallel state.

Normally, a slight net excess of dipoles align in the lower-energy (parallel) direction in contrast to the higher-energy (antiparallel) direction. The excess is referred to as the *net magnetization*. This excess generates the signal measured in the MRI experiment.

Net magnetization increases with field strength, as does the difference in energy level between the parallel and antiparallel states. For these reasons, MRI signal strength increases in proportion to the external magnetic field. Thus, magnets with higher field strength are needed to increase the strength of the emitted signal. In clinical imaging, only one or two protons out of each million are in the parallel state versus the antiparallel state. Thus, only a small portion of the total pool of nuclei participate in the generation of the MRI signal.

The precession frequency of a magnetic dipole in an external field depends on the strength of the field. This

frequency is specific for each nuclear species and is related to the field strength by the following formula:

$$f_{\text{Larmor}} = \gamma B_0$$

where

f_{Larmor} = the Larmor or resonance frequency

B_0 = the applied magnetic field strength

γ = the gyromagnetic ratio

The resonance frequency at 1.5 T is 64 MHz and at 1.0 T is 42.6 MHz. Hence, γ is 42.6 MHz/T for protons. Other nuclei have different gyromagnetic ratios. A shift of the net magnetization from the parallel to antiparallel state can be achieved by supplying energy to the spins in the form of an RF field at the Larmor frequency. When the applied RF field is removed, the magnetic dipoles return to their equilibrium state by releasing the previously applied RF energy. The release of this energy is also at the Larmor frequency. Prior to their return to alignment parallel to the static magnetic field, the magnetic dipoles precess about the field at the Larmor frequency, thereby creating a time varying magnetic field, much like that produced by a spinning bar magnet.

Perturbation of the net magnetization by applying an RF field at the resonance frequency and the measurement of its precession about the static field and its return to equilibrium is the underlying principle behind the MRI equipment.

Figure 2-2. In the absence of an external magnetic field, magnetic dipoles are randomly oriented, resulting in a zero net magnetic field.

Figure 2-3. The introduction of an external magnetic field (B_0) forces the magnetic dipoles to align in one of two states: parallel (low energy) or antiparallel (high energy). A small excess in the parallel direction results in a nonzero net magnetic field (M).

Principles of Magnetic Resonance

Consider a simple analogy for the (resonance) phenomenon that underlies the MRI experiment. Resonance is manifested by enhanced and relatively abrupt absorption of energy occurring at a particular frequency.

For example, water contained in a glass goblet begins to vibrate or resonate and emits a sound if a tuning fork of the correct frequency is struck and placed near it. Imagine a goblet that contains an appropriate volume of water (e.g., 100 mL) to “ring” at pitch A. Now imagine an oscillating tuning fork, also oscillating at this frequency, placed nearby. Even though the tuning fork is not placed in contact with the goblet, the vibration of the nearby air molecules causes the goblet to also begin to vibrate because the tuning fork and the goblet have the same resonant frequency. We can observe the vibration of the water by seeing movement of the surface, heard as the sound corresponding to pitch A, or detected as a signal by an oscilloscope. The oscilloscope displays an image of what is heard in graphic form. The number of oscillations per second is a measure of the frequency of the goblet vibration, and the amplitude of the oscillation is a measure of its loudness.

If 100 goblets are placed on 10 shelves within a cabinet with opaque walls and each goblet contains 100 mL of water, as in the previous example, the peak amplitude of the signal displayed on the oscilloscope will correspond to their total loudness and will thus be a function of the entire number of goblets in the cabinet. Increasing or reducing the amount of water in the goblet modifies the resonant frequency (Fig. 2-4). However, the resonance phenomenon

(i.e., vibration of the goblet) occurs only if the resonant frequency of the tuning fork matches that of the goblet.

In clinical MRI, the atomic nuclei are analogous to the goblets. The amount of water in the goblet corresponds to the strength of the external magnetic field. The tuning fork is analogous to the RF pulse. Thus, an MRI resonance, and thus the voltage, can be detected in a receiver if the frequency of the RF pulse matches the resonant frequency of the nuclei at that magnetic field strength.

The frequencies of interest in MRI are much higher than those used in our analogy and are usually expressed in megahertz (MHz) or millions of cycles per second (Hz). For example, hydrogen nuclei in a 1.0 T magnetic field resonates at a frequency of 42.6 MHz. Other MRI-sensitive nuclei have different resonant frequencies, just as differently shaped goblets, when filled with the same volume of water, also have different resonant frequencies. With the appropriate equipment, it is possible to measure signals from these other nuclei in vivo.

The initial stimulus in clinical MRI is provided by a burst or pulse of RF energy at the appropriate frequency, comparable to the effect of the tuning fork at a given tone. The nuclei resonate at that same frequency, and the amplitude of their emitted signal after removal of the stimulus reflects the number of nuclei contributing to the signal. Again, the electromagnetic oscillation induced in the receiver or detector is matched (i.e., it is tuned) to the frequency of the resonating nuclei in the same way that a radio is tuned to a specific frequency to detect a specific station.

To continue our analogy, imagine that every position, right to left, within the cabinet vibrated at a different frequency following the initial resonance phenomenon that caused it to start vibrating. Those goblets on the rightmost corner are at the highest frequency; those at the left side

Figure 2-4. Analogy for the resonance phenomenon. Tuning forks with specific frequency (f_3) are placed in proximity to goblets with different water levels and resonance properties. Only the goblet whose resonance frequency matches frequency of the tuning forks absorbs and subsequently emits energy.

are at the lowest frequency. The sound, heard as a whole, is the sum of the component sounds emitted by each goblet at each position.

A mathematical technique, the Fourier transformation, is then employed to sort each component's amplitude and frequency. In this way, positional information regarding the location of the goblets is available because of the one-to-one relationship between spatial location and frequency of the sounds present. The number of goblets at each position is determined from the amplitude of the sound at each frequency. Thus, the positions of the goblets and number of goblets at each position can be determined even though the goblets are located in a cabinet with opaque walls and so cannot be observed directly.

The same phenomenon is used in MRI when a magnetic field gradient is applied following the resonant excitation of the RF pulse in order to establish a one-to-one mapping between position and precessional frequency. The magnetization's voltage is Fourier transformed to tell us at which locations (i.e., frequencies) protons are present and how many are at each location.

Radiofrequency and the MRI Experiment

For convenience, the direction of the external applied magnetic field (B_0) is along the z-axis. The transverse plane is perpendicular to the main field and contains the x-axis and the y-axis. The small net excess of dipoles aligned in the lower-energy parallel position are represented by a net

magnetization vector (M) located along the z-axis in the direction of the field.

Application of the RF pulse causes each proton's magnetic moment aligned along the z-axis to rotate away from it, thereby causing the net magnetization vector to also rotate away from the z-axis. The amount of rotation is referred to as the *flip angle*. The greater the strength and duration (i.e., the greater the energy delivered by the RF pulse, the greater the flip angle). The flip angle is user-selectable, with the choice determined by the particular imaging sequence.

For spin-echo imaging, one would use a 90-degree RF pulse, which by definition is a pulse of sufficient strength to rotate M so that it is flipped from the z-axis to an orientation entirely in the transverse plane. This transverse component of M is entirely responsible for the MRI signal. Within this plane, M precesses around the z-axis at the Larmor frequency, returning to its equilibrium state by releasing energy to its environment in a process called *relaxation*. A receiving antenna or coil can be used to detect the time varying magnetization during precession. The resulting signal is referred to as a *free induction decay* (FID) (Fig. 2-5).

Relaxation

The maximum longitudinal magnetization along the z-axis is known as the *equilibrium magnetization*; for a given field strength and temperature, it is directly proportional to the proton density (ρ). The return of nuclear magnetization

Figure 2-5. Diagrammatic representation of a basic MRI experiment. A, In the absence of an external magnetic field, net magnetization (M) is zero. B, Net magnetization is created by the application of an external static magnetic field (B_0). C, The application of energy, in the form of a 90-degree radiofrequency (RF) pulse, “tips” the magnetization vector onto the x-y plane. D, The precessing magnetization decays exponentially back to equilibrium (+z). The amplitude of the x-y component of the magnetization versus time (free induction decay [FID]) is shown. E, The system is back at equilibrium.

(M) after an RF pulse to its low-energy or equilibrium position along the z-axis is the result of interactions between the nuclei and the local electrochemical environment, its surrounding nuclei, and the strength of the B_0 field. The return of the magnetization to its equilibrium alignment and equilibrium value follows an exponential function of time. Because different tissues create different physical and electrochemical environments, their relaxation occurs at different rates, and their exponential recoveries are described by their relaxation times, T_1 . Hence, different tissues have different T_1 s.

As noted earlier, once the magnetization M is tipped into the transverse plane, an FID (induced voltage from the magnetization free of the RF pulse) is obtained. Careful examination of the FID reveals that its amplitude decreases exponentially with time. Hence, the transverse magnetization can be shown to also relax, and a parameter, T_2 , is used to describe the rate of this exponential loss of signal in the transverse plane. Different tissues have different T_2 s, just as they differ in T_1 and proton density. Therefore, the strength of the MRI signal at any time during its induction is dependent on three parameters—proton density, T_1 , and T_2 ; these parameters are responsible for the contrast in MRI images.

T_1 Relaxation

Any input of RF power that tips the magnetization vector, M , away from the z-axis reduces its intensity along the z-axis to some value between the maximum and the negative of the maximum. Following cessation of the RF pulse, the nuclei return toward their equilibrium magnetization, M rotates from the x-y plane to the z-axis and M returns to the initial magnetization at some finite time later. The process of returning toward the equilibrium magnetization constitutes T_1 relaxation, or *longitudinal relaxation*.

When a 90-degree RF pulse rotates M into the x-y or transverse plane, the entire vector is located in that plane, and its value along the z-axis is zero. The value slowly returns from zero to its initial strength, according to a simple exponential time constant such that its value after one T_1 interval is 63% of the maximum value and reaches 99% at $5T_1$ (Fig. 2-6A). The process is caused by release of energy into the surrounding tissue (i.e., into the molecular environment or lattice around the proton). Hence T_1 relaxation is also referred to as *spin-lattice relaxation*.

The return of longitudinal magnetization with time can be plotted as a curve, which has an exponential shape toward an upper limit. Thus, the difference between the curve's initial and final height is always a fixed proportion of the displacement from the maximum value, and the length of time taken to move from any point on the curve to one that is 63% closer to equilibrium is identified as the *time constant* (T_1) for that curve. The Bloch equations summarize these observations and describe the regaining of *longitudinal magnetization* after an RF pulse.

Among the factors that influence the T_1 value of a tissue are:

1. The particular chemical substance and its physical state.
2. Field strength (T_1 increases with field strength, therefore recovery is slower).

Figure 2-6. A, Exponential recovery of z magnetization after 90-degree pulse. The rate of recovery is dependent on T_1 . B, Exponential decay of x-y magnetization after 90-degree pulse. The rate of recovery is dependent on T_2 .

3. Temperature (longer T_1 with increased temperature in biological samples).
4. The liquid surrounding the protons.
5. The mobility of the proton; for example, protons in bone are much less mobile than those in water.

In imaging, RF pulses can be specifically designed to maximize or minimize image contrast dependence on T_1 differences. The finite length of T_1 limits how rapidly the RF pulses can be repeated and still yield a measurable MRI signal; that is, sufficient time must exist for longitudinal magnetization to regrow between pulses. Varying the strength and repetition time of RF pulses allows one to maximize or minimize the contrast between tissues with different T_1 properties. With short *repetition times* (TRs), differences in magnetization are largely dependent on T_1 differences, whereas the dependence at long TRs (hence following long recovery times) is due primarily to differences in proton density only.

T_2 Relaxation

Immediately following a 90-degree RF pulse, the individual magnetic moments are all located in the transverse plane; more important, however, they are *coherent* (pointing in the same direction at nearly the same frequency). In other words, all protons have the same rotating phase.

Because the FID is the sum of voltages from many protons at each spatial location, the protons must precess at the same frequency and with the same alignment so that their magnetizations work together. As time goes on, following the RF excitation pulse the individual magnetic moments begin to become spread out in the transverse plane, much like cars of different speed on a race track. One cause of the different speeds is due to small local

variations in the static magnetic field resulting from random interactions from the magnetic moments of nearby protons. It is this spreading out that causes the vector sum to decrease. With time, therefore, the individual spins exchange energy between themselves until eventually they become completely incoherent, or *dephased*. Thus, T2 relaxation is also referred to as *spin-spin relaxation*.

The signal totally disappears when all phase coherence is lost. A curve that plots the disappearance of the signal with time shows an exponential decay toward zero, and the time taken for the signal to lose 63% of its initial intensity represents its time constant and is the T2 value for that substance, or *transverse relaxation* (Fig. 2-6B). T2 limits the time during which the signal is available after an RF pulse and thus limits the period of observability of the signal. This relaxation effect is also described by the Bloch equations. Thus, the dephasing resulting from interaction between adjacent spins is referred to as *T2 relaxation*.

Dephasing also occurs from local imperfections in the magnetic field and in thermal noise. All sources of dephasing—spin-spin and local inhomogeneities—are included in the single term $T2^*$, pronounced “tee-two-star.” Fortunately, different tissues have different T2s. In clinical applications, T2 relaxation is exploited to produce image contrast.

T1 and T2 relaxations occur simultaneously, although T2 relaxation is a much more rapid process. T1 relaxation is field-dependent and increases with field strength; T2 relaxation is less dependent on field strength because it depends mainly on molecular interactions that occur at a much lower rate than the resonance frequency. Hence, imaging protocols developed at one field strength will exhibit differences in image signal-to-noise (SNR) ratio and image contrast if they are attempted at other field strengths owing to differences in T1 relaxation rates at different fields.

The phenomenon of signal decay and recovery in MRI may be summarized as follows. The T1 and T2 values for a substance are its time constants for acquiring or reacquiring its equilibrium state. The longitudinal magnetization of a substance (i.e., its ability to produce a signal) grows along the T1 curve after any disturbance in the equilibrium magnetization. A 90-degree RF pulse rotates all the longitudinal magnetization into the transverse plane, where T2 dephasing can also be observed. Basic differences in signal recovery as a result of different T1 and T2 values in the body tissues create differences in the magnetization vector of these tissues (Figs. 2-7 and 2-8).

The time constant for the substance to lose irreversibly its transverse magnetization represents its T2 value. The loss of transverse magnetization cannot be slower than the gain in longitudinal magnetization and, in fact, can happen more rapidly, especially when there is loss of phase coherence.

The Imaging Process

The steps involved in the production of an MRI study may be summarized as follows:

1. A powerful, uniform, external magnetic field is employed to align a small but measurable fraction of the

Net Z-axis Magnetization vs. Time

Figure 2-7. Exponential recovery of z magnetization after 90-degree pulse for two substances. The difference between the two curves determines contrast.

normally randomly oriented water proton's nuclear magnetic dipoles contained in the tissue being examined. Some of the randomly oriented nuclei lose energy to the lattice via T1 relaxation, causing a net magnetization to develop.

2. Next, this alignment (or magnetization) is perturbed or disrupted by introduction of external RF energy at an appropriate frequency so as to induce resonance. Spatial localization is obtained through application of a spatially dependent magnetic field (*gradient*) during the same time that RF energy is introduced into the tissue. The gradient field selectively modulates the resonant frequency of the patient in accordance to the Larmor equation (Fig. 2-9).
3. The nuclei return toward their initial alignment and precess about the static magnetic field. The magnetization along the static field grows while the precessing signal (and hence precessing magnetization) decreases through various relaxation processes. While the magnetization is precessing, the time varying magnetization induces a voltage in a receiver coil.

Net Magnetization In the x-y Plane vs. Time

Figure 2-8. Exponential decay of x-y magnetization after 90-degree pulse for two substances. The difference between the two curves determines contrast.

Figure 2-9. A z-axis slice selection using gradient field. Value of the net field ($B_0 + \text{gradient}$) at any given z value determines the resonant frequency. Radiofrequency excitation at a given frequency excites only a specific location.

- After an appropriate period following initial RF deposition, the emitted signals are measured or read out during application of additional magnetic field gradients (typically measured in milliTesla per meter [mT/m]).
- A mathematical process called *Fourier transformation* is used to convert the frequency information contained in the signal from each location in the imaged plane to corresponding intensity levels, which are then displayed as shades of gray in a matrix arrangement of, for example, 256×256 pixels.
- Protons in the various tissues in the imaged slice realign with the magnetic field at (via T1) or decay in the transverse plane (via T2) at different rates, so that at any given moment there is a difference in signal strength between various tissues. This difference in signal strength from region to region constitutes the basis of tissue contrast and forms the substrate for interpretation of the image.

Radiofrequency Pulses

The RF energy used to perturb the protons as they align in the external magnetic field is delivered as a burst of input energy referred to as the *RF pulse*. The pulse consists of a signal at a fixed frequency, duration, and amplitude. The duration is typically a few milliseconds, and the amplitude, or power, is usually given in kilowatts. The strength of the applied RF field is on the order of microTesla (millionths of Tesla).

As the RF pulse tip angle is increased, the strength of the observed signal (i.e., the net portion of the equilibrium magnetization oriented along the x-y plane) reaches a maximum, after which further increases in the input power produce progressively less signal each time. This continues up to a point at which a pulse with a duration twice that of the one producing the maximum signal produces no signal at all.

The smallest power of the RF pulse input that produces a maximum response in the evoked signal is called the *90-degree pulse* (or a $\pi/2$ pulse). This pulse tips the transverse magnetization to the x-y plane.

A pulse with twice that strength that produces no evoked signal is called the *180-degree pulse* (or a π pulse). This pulse tips the transverse magnetization antiparallel to equilibrium (the $-z$ direction). If the magnetization is already in the transverse plane, the 180 degree RF pulse will cause the magnetization to “pancake flip” over.

The RF transmitter is turned off or inactivated when one wishes to detect the MRI signal (on the order of nanoTesla or billionths of Tesla) so that the much stronger RF pulse does not mask the small MR signal. In the typical MRI study, several hundred signals are collected, so that the study usually consists of a series of events with the following order: RF pulse, read after some time (echo time [TE]), wait for some longitudinal recovery to occur (repetition time [TR]); RF pulse, read, wait. . .

Each series is a repetition of the one preceding in the order and timing of the RF pulses used. The particular combination is referred to as the *RF pulse sequence*. Several pulse sequences are discussed later.

Magnets and Field Gradients

The variation of any physical quantity with distance is referred to as a *gradient*. For example, in a harp, the strings nearer the performer are shorter than those farther away. Each string is spaced at a uniform distance from the one preceding it. In the water goblet example, positional information can be derived by knowing the frequency of a signal. In MRI studies, field gradients are employed to make the MRI signal contain spatial information. The gradient magnetic field spatially alters the resonant frequency of the imaging volume in accordance to the Larmor equation (see Fig. 2-9).

A typical variation in applied field strength-static magnetic field (B_0) + gradient magnetic field-across the imaging volume is approximately 100 gauss (G) (0.01 T). Thus, for a 1.0 T magnet, the magnetic field superimposed on the main magnetic field for spatial encoding spreads the proton resonance frequency out over a range that spans 0.4 MHz or less. Recording the frequencies over this entire range and spatially decoding using the Fourier transform achieve precise localization of their source.

The gradient field is superimposed on the main magnetic field through employment of gradient coils: three orthogonal sets of coils, one each for the x-axis, the y-axis, and the z-axis. The gradients produced by these coils are spatially linear and produce a difference in field strength such that the difference between any two planes in the imaged volume is directly proportional to the distance between those planes. The nuclei at the weak end of the field resonate at a lower frequency, and those at the stronger end resonate at a slightly higher frequency. Because resonant frequency is directly proportional to field strength, imposing a linear field gradient on a magnetic field makes the resonant frequency of the nucleus vary linearly across the volume. By having an orthogonal arrangement of gradient coils, one can achieve linear gradients in any desired direc-

tion and thus can create a series of parallel planes with linearly decreasing field strength.

The amplitude and direction of the gradient are thus user-selectable. Each gradient coil is connected to an amplifier that supplies current to create the field variation. The amplifier can be turned on and off and applied at different strengths so that the gradients also become time-dependent. Because the coils are independent and used to define orthogonal scan planes, it is possible to acquire oblique scan planes electronically without physical reorientation of the patient or the hardware, simply by providing appropriate gradient waveforms to combinations of the gradient coils.

Gradients, Field of View, and Resolution

As noted earlier, each gradient coil is connected to an independent amplifier and the amount of current that the amplifier provides produces a proportionate alteration in the strength of the gradient field. It can be shown that:

1. For a fixed RF pulse, the minimum slice thickness is directly proportional to the maximum gradient strength.
2. For a fixed signal sampling time and image matrix size, the minimum field of view (FOV)—and, hence, minimum resolution—is directly proportional to the maximum gradient strength.
3. The minimum TE and minimum TR of a sequence depend on the time it takes for the gradient waveform to go from zero amplitude to its final value. The parameter that describes the MRI system's rate of change of the gradient field is the *slew rate*, given in mT/m per msec. Typical values for a common system today are near 50 mT/m per msec; typical gradient strengths for a whole body system are on the order of 25 mT/m per msec.
4. The sensitivity of the gradient coils in producing the desired field is related to the amount of field produced per unit of current. This sensitivity is related to the size of the coils, whether they are self-shielded and the spatial arrangement of the conductors that make up the coil.

These relationships establish a number of interesting possibilities. For example, the FOV along the phase encoding direction is governed by the size of the change in gradient pulse from one TR to the next. Because this is independent of the read gradient sampling, the FOV in the phase encode and read gradient can be specified independently, as can the resolution along the two axes.

Imagine that the torso is being imaged. In most people, the width of the torso (left to right [L-R]) is greater than its height. Hence, a 400-cm FOV may be required along the R-L read direction; only 300 mm is required along the anterior-posterior (A-P) phase-encode direction by acquiring a 400×300 mm FOV image (i.e., rectangular FOV). The phase-encoding resolution is equal to FOV/N_y , where N_y is the number of phase encoding steps. Hence, N_y can be reduced if the FOV is reduced from 400 to 300 mm, thus saving acquisition time. The only sacrifice is a small loss in the image's SNR ratio, since the SNR is proportional to $\sqrt{N_y}$ at constant resolution. Additionally, it is possible to alter the number of phase-encoding steps so as

to alter the resolution such that it differs along the read and phase directions.

The gradient coils are essentially large inductors. Thus, to have the system go from zero gradient strength to the desired spatial magnetic field gradient, current must be applied to the gradient coils. The rate of change of the gradient field, or slew rate, is related to the rate of change of current. In electric circuits, the voltage across an inductor (gradient coil) is related to the inductance of the coil and the rate of change of the current (hence the slew rate of the gradient field). Thus, gradient amplifiers must produce hundreds of amps of current throughout the acquisition and at hundreds of volts during the ramping of the gradient. In very rapid sequences, such as in *echo-planar imaging*, which can achieve a complete acquisition in approximately 100 msec, the MRI gradient subsystem may be asked to produce up to 0.25 MW of power along each of the gradient axis, yet the total energy delivered may be only a few thousand kilojoules.

In many discussions of MRI pulse sequences, the various gradient lobes required are drawn as instantaneous changes in the amplitude of the gradient. In reality, however, the slew rate of the imaging system prevents this. Hence, in actual MRI pulse sequences, the gradient lobes ramp-up from some value to that required for achieving the specified field of view or slice selection thickness. Figure 2-10A shows the difference between real and symbolic pulse sequence gradient lobes.

Pulse Sequences

MRI pulse sequences in clinical use can be grouped into three basic classes:

- Spin-echo sequences
- Inversion recovery sequences
- Gradient-echo sequences

Many techniques have been developed using these basic sequences, thus covering a broad range of mechanisms for generating contrast between tissues.

Spin-Echo Sequences

A 90-degree pulse is applied to tip the spins into the x-y plane. As previously described, the rotating bulk magnetization vector M generates a signal (the FID). The initial strength of the FID diminishes because of loss of coherence between the precessing protons in the tissue of interest. This loss of coherence arises from spin-spin relaxation (T_2) and local field inhomogeneities (T_2^* effects), which cause the protons to rapidly spin out of phase with each other.

In spin-echo sequences, the FID is not of interest and is ignored. A second 180-degree RF pulse is applied a short time after the 90-degree pulse. The time between these two pulses is usually referred to as τ . This second 180-degree pulse rephases the portion of the protons that had lost coherence because of time-independent, static magnetic field inhomogeneities. The signal arising from this rephasing peaks at a time, τ , after the 180-degree pulse and is called a *spin echo*. The time between the application of the initial 90-degree pulse and the peak of the spin echo is referred to as the *echo time*, or TE (Fig. 2-10B). It

Figure 2-10. A, The difference between ideal and real gradient waveforms is a result of the finite slew rate of the MRI systems. Each gradient waveform takes a finite, rather than an infinitesimal, time to reach the final gradient strength. B, Timing diagram for spin-echo pulse sequence. TE, echo time.

essentially is equal to the time from generating the transverse magnetization until the center of the signal acquisition (see earlier).

Repeated with a long interval between the excitation pulses, the $90^\circ\text{-}\tau/180^\circ\text{-}\tau$ sequence produces an image whose strength is dependent on the proton density and the T2 of the tissue alone (T2-weighted). If the TE is short such that little dephasing occurs and with a short interval between repeated acquisitions, the image will be primarily dependent on variations in T1 between tissues (T1-weighted). Long TRs corresponding to full recovery of the magnetization (and hence limited variation due to T1 differences) and short TE corresponding to little signal loss from T2 decay, provide an image that is primarily dependent only on proton-density differences between tissues. Examples of T1, proton density, and T2-weighted images of a normal brain are shown in Figure 2-11A–C.

Fast (Turbo) Spin-Echo Sequences

In a conventional spin-echo pulse sequence, the 180° -degree pulse allows the magnetization dephasing from field inhomogeneities to be recovered and to thus generate an echo of the initial transverse magnetization. The total imaging time is given as $TR * NSA * Ny$, where NSA is the number of signal repetitions that are averaged together and Ny is the number of phase-encoding steps performed.

The spatial resolution along the phase-encoding axis is given by FOV/Ny . If additional 180° -degree pulses were applied, additional echoes would be obtained after the first one. These additional echoes can be combined in a few different ways. For example, if additional phase encoding is performed prior to each echo, each collected signal

acquires a different one of the Ny encodings. The total imaging time is reduced because multiple phase encodings are performed after each 90° -degree pulse. That is, the number of echoes (echo train length [ETL]) is acquired for each TR; echo train length is the number of echoes per TR. The total imaging time under these conditions is $TR * NSA * Ny/ETL$ and, hence, represents a reduction in the imaging time when compared to a conventional spin-echo acquisition. These acquisitions have become known as “turbo spin-echo,” or fast spin-echo scans.

A different way to use the multiple echoes is to perform no phase encoding for each echo and to collect each echo as one view for an image at a new TE. In this way, multiple images are obtained over $TR * NSA * Ny$, each acquired at a different TE. This technique has been widely used to acquire a short TE and a long TE acquisition at a long TR so that both proton-density weighting and T2-weighted scans are acquired in the imaging time.

Inversion Recovery Sequences

Various modifications of this standard spin-echo technique have been developed to provide enhanced contrast for many tissue and disease types. One example is the *inversion recovery (IR) technique*. In this sequence, a 180° -degree inversion pulse is applied some time before *inversion time (TI)*, the standard 90° - to 180° -degree spin-echo sequence previously described. The 180° -degree inversion pulse flips the equilibrium magnetization vector M so that it is antiparallel to the field.

Following this pulse, the spins begin to revert to equilibrium by transferring energy to the surrounding medium (or lattice). The z-axis component of the magnetization shrinks

Figure 2-11. Identical 10-mm axial sections of the brain obtained using a spin-echo sequence. *A*, TR = 500 msec, TE = 20 msec. White matter appears brighter than gray; this is especially apparent at the cerebral cortex. *B*, TR = 2000 msec, TE = 20 msec. Gray and white matter are nearly isointense. *C*, TR = 2000 msec, TE = 100 msec. Gray matter is brighter than white matter (contrast reversal from sequence used for *A*).

from the antiparallel direction to zero, after which it regrows into the equilibrium (aligned) direction exponentially with the constant T1. Measurement of the magnetization *M* at some time *TI* after the initial 180-degree pulse via the 90- to 180-degree excitation of the partially recovered longitudinal magnetization and detection of the created transverse magnetization provides a measure of the T1 recovery of the tissue. Simple alteration of *TI* values allows for the selection of different T1 contrast points.

STIR Imaging

The time that it takes the longitudinal magnetization to reach zero is $\ln(2) \cdot T1 \sim 0.7 \cdot T1$. This technique to

eliminate the signal from one tissue in an image has been used in two different applications. Fat, which has a T1 of approximately 240 msec at 1.5 T, can be eliminated from the image by using a *TI* of approximately 170 msec. Known as *short tau inversion recovery* (STIR), these acquisitions have been widely used in musculoskeletal and body MRI.

Figure 2-12A shows an example of a T1-weighted acquisition of the lower leg via a conventional spin-echo acquisition and an inversion recovery sequence with spin-echo read out in which the signal from fat is removed. Note the difference in contrast in the marrow, the site of the actual disease, once the fatty component is removed

Figure 2-12. Inversion recovery sequences can be designed to generate transverse magnetization when the longitudinal magnetization has relaxed to zero following an initial inversion. *A*, Conventional T1-weighted spin echo. *B*, Conventional T1-weighted short tau inversion recovery (STIR) in which the signal from fat is removed. Note the appearance of a significant signal in the marrow once the fatty component is removed. *C*, Conventional T2-weighted spin echo. Note the high signal amplitude in the ventricles. *D*, Fluid-attenuating inversion recovery (FLAIR) acquisition in which the basic contrast between tissues in the parenchyma is unchanged from the original T2-weighted spin echo, except for the loss of the cerebrospinal fluid (CSF) signal.

via the STIR acquisition designed to eliminate the fat component (Fig. 2-12B).

FLAIR Imaging

The second application for signal suppression is in brain imaging, in which T2-weighted acquisitions have found great application in providing enhanced signal for pathologic processes due to edema and increased T2s in these tissues. Unfortunately, the T2 of cerebrospinal fluid (CSF) is also long, making identification of pathology in the parenchyma adjacent to the ventricles difficult as a result of high-intensity signal from both the pathology and the CSF in immediate contact.

Fluid-attenuating inversion recovery (FLAIR) methods have been developed in which the TI is approximately 2000 msec or so (the T1 of CSF is 2000 to 4000 msec) so that the CSF signal is eliminated at the time of the 90-degree pulse for the long TE spin-echo pulse sequence. Figure 2-12C and D provides a comparison of a conventional T2-weighted spin echo and a FLAIR acquisition at the same location. Adjacent to the ventricles, the high-signal amplitude of the CSF is removed and would permit visualization of "bright" signal, if present, in the brain parenchyma.

Gradient-Echo Acquisitions

Gradient-echo sequences replace the 180-degree refocusing RF pulse of the spin-echo sequence with a fast reversal of the magnetic field gradient (Fig. 2-13). The initial portion of the refocusing gradient places the protons along the applied gradient in different strength magnetic fields, causing differences in the precessional frequency and hence dephasing of the magnetization. The second portion of the gradient reverses the dephasing of the protons by rapidly reversing the gradient direction, forcing the nuclei back in phase and generating an echo.

The 90-degree RF pulse used in the initiation of the spin echo is replaced by a different (and variable) strength RF pulse. Depending on the strength of the pulse, the magnetization vector is rotated toward the x-y plane. The

amount of rotation resulting from this pulse is called the *flip angle*.

Fast (Spoiled) Gradient-Echo Acquisitions

In normal spin-echo and IR pulse sequences, it can be safely assumed that the transverse magnetization has decayed to zero prior to the application of the next RF pulse at the end of TR. This is not necessarily true in gradient-echo acquisitions in which the TR may be very short. This has led to two types of gradient echo acquisitions: (1) those that *utilize* the residual transverse magnetization available at the end of TR and (2) those that *spoil* it. These two types of sequences have very different contrast characteristics as a function of the pulse sequence parameters.

The variation of the flip angle is an important factor in creating contrast differences and shortening imaging time. In spoiled acquisitions (e.g., FLASH, spoiled GRASS), the degree of "T2-weightedness" of the signal varies roughly with the flip angle. The smaller the flip angle, the more the gradient-echo image looks "T2-like," since the influence of spin-lattice relaxation differences is minimized. Short times between pulse repetitions are made possible also by the use of small flip angles, because longitudinal magnetization has been altered only slightly with small tip angles, sufficient time to recover and return to equilibrium.

An additional twist to the gradient-echo techniques can be achieved by using a spoiler gradient or random-phase RF pulse to eliminate the transverse component of the "steady-state" magnetization. This method results in T1-weighted images (at flip angles of 30 degrees or more). Another common name for these sequences is T1-FAST.

Short TE times are usually used in gradient-echo sequences to minimize the effect of static field inhomogeneities within the volume of interest. Unlike the spin-echo sequence, the gradient echo does not compensate for the effect of time-independent magnetic field homogeneities; hence, gradient-echo images are essentially T2*-weighted images.

Table 2-1 describes various scan sequences and their appearance for different tissues.

Unspoiled Fast Gradient-Echo Sequences

In our previous discussion, and in the presentation of contrast versus sequence parameter given in Table 2-1, it is assumed that the time between excitations is sufficiently long that transverse magnetization is sufficiently decayed ($TR > T2$). If this is not the case, steady-state effects must be taken into account because their effect on contrast can be significant. For these short TR cases, the RF pulse alters the residual transverse magnetization as well as the partially recovered longitudinal magnetization. A steady state of unrecovered magnetization is maintained by the fast repetition. This different (from fully recovered) initial magnetization can be manipulated to provide additional contrast possibilities. Depending on the manufacturer, these sequences go by the names FAST, GRASS, or FISP. The longitudinal component of the magnetization is dependent on the steady-state magnetization which is, in turn, dependent on the amount of T2 decay between pulses.

Figure 2-13. Timing diagram for gradient-echo pulse sequence.

Table 2-1. Tissue Characteristics for Various Scan Sequences

Sequence	Parameter	Parameter	Contrast Type (Weighting)	CSF	Gray Matter	White Matter	Fat	Muscle	Disk
Spin echo	Long TR	Short TE	Spin density	Gray	Isointense	Gray-black	Bright	Isointense	Bright gray
Spin echo	Short TR	Short TE	T1	Dark	Gray	Bright gray	Bright	Isointense	Isointense
Spin echo	Long TR	Long TE	T2	Bright	Gray	Black	Gray-black	Gray-black	Bright
Inversion recovery		Long TE	T2	Bright	Gray	Black	Gray-black	Gray-black	Bright
Inversion recovery	Short T1	Short TE	T1	Dark	Gray	Bright gray	Bright	Isointense	Isointense
Gradient echo	Flip angle $<20^\circ$	Long TE	T2	Bright	Gray	Dark	Gray-black	Isointense	Isointense
Gradient echo	Flip angle $>45^\circ$	Short TE	T1	Dark	Gray	Bright gray	Bright	Gray-black	Bright

CSF, cerebrospinal fluid; TE, echo time; TR, repetition time.

Three-Dimensional Gradient-Echo Acquisitions

In most conventional acquisitions, the imaged volume results from signal from distinct planes excited by the selective RF pulses applied in the presence of a magnetic field gradient. At soon as the signal from one slice is collected, excitation of the next spatial location can occur. In this way, the acquisition of slice information is interleaved in time within the TR. The acquisition time largely appears independent of the number of slices acquired.

In rapid gradient-echo acquisitions, TR is very short (i.e., on the order of tens of msec versus hundreds or thousands of msec or less), thereby leaving little time for slice interleaving when multiple slices are needed. A different mechanism is used to obtain information over the image volume. In three-dimensional (3D) gradient echo acquisitions, instead of information being acquired from distinct planes, signal is obtained from the entire imaging volume for each acquisition. Frequency encoding and phase encoding are performed along the image planes as in a typical acquisition, yet an additional phase encoding is also applied along the slice select direction. Excitation is performed over a slab instead of a slice, and the phase encoding along the slice select direction subdivides the signal in this direction just as it does in conventional MRI. Thus, in 3D acquisitions, image resolution along the slab-select direction is not dependent on the slice select RF pulse bandwidth and the gradient strength but, instead, on the slab thickness and the phase-encoding gradient process, just as the phase-encoding process determines the image resolution along the phase-encoding axis in a two-dimensional (2D) image.

A 2D and a 3D pulse sequence is shown in Figure 2-14. Because phase encodings are performed along multiple axes, the total acquisition time becomes $TR * N_y * NSA * N_z$. Typical values for N_y in any acquisition are 128 to 512, whereas N_z for a 3D acquisition may vary from 4 to 256. Although the acquisition time in 3D acquisitions seems to be N_z times longer in a 3D gradient-echo than a spin-echo acquisition, the TRs in these sequences are typical only a few milliseconds in duration in comparison to the hundreds or thousands in spin-echo methods. The advantages of a 3D acquisition are the high spatial resolution along the slab select direction and the wide range of contrasts available from spoiled or unspoiled gradient-echo sequences.

Review and Integration

Any MRI study directly shows received signal amplitude as a function of position. For a given pixel, amplitude depends on the (1) T1, T2, and proton density of the substance being imaged; (2) motion, such as flow; (3) system noise, and (4) pulse sequence used.

Most components of the body contain approximately similar quantities of hydrogen and, therefore, have similar equilibrium magnetization. Air spaces are an exception. The MRI signal elicited in solids disappears extremely rapidly (often within microseconds) and can take hours or days to reestablish equilibrium magnetization. Thus, solids have a long T1 and a short T2. The solid tissues encountered in clinical practice are cortical bone, tooth enamel, and dentin. Conversely, in liquids potential signal can be

Figure 2-14. A 2D gradient-echo sequence consists of a radiofrequency (RF) slice selection and phase encoding along a separate axis. The read gradient is used for encoding along the third image axis. The RF pulse excites a thin slice of tissue, and signal only comes from that slice. In a 3D sequence, a weaker gradient pulse is used to excite a slab of tissue. The slab is then subdivided by a phase encoding, also performed along the slice direction in a manner comparable to dividing the field of view with the phase-encoding gradients in a normal sequence. A 3D Fourier transform reconstruction is used.

regained almost as quickly as actual signal is lost; that is, T_2 approaches T_1 and the value for both is on the order of milliseconds to seconds.

The remaining body components are tissues that are neither entirely solid nor liquid. They have a higher viscosity than liquids and less crystalline structure than solids. Making a liquid more viscous would shorten its T_1 . The T_2 cannot be longer than T_1 , and thus viscous liquids have short and roughly equal T_1 and T_2 . If the viscosity increases further, the substance becomes more like a solid, and T_1 is longer than its T_2 . In clinical imaging most tissues have a T_1 between 200 msec (fat) and 3 or 4 seconds (CSF). The T_2 values lie between 30 msec (muscle) to about 2 or 3 seconds (CSF). Cortical bone and teeth are exceptions in both cases and are not typically seen in images because of low proton density and relaxation times that hinder signal detection and generation.

For a given field strength and a constant temperature, the strength of a substance's equilibrium magnetization is directly proportional to its proton density (p). In imaging objects that are not chemically uniform, such as the brain, in which all tissues have essentially the same proton density and therefore the same equilibrium magnetization, one can exploit the difference in T_1 values. Plotting the curve of longitudinal magnetization versus time, all curves start at zero value following the 90-degree pulse and recover longitudinal magnetization along their own T_1 . After a long waiting period the magnetization will be near maximum for each; each pixel value will also be near its maximum, and the pixels will be uniformly bright over the whole image, provided that T_2 differences are minimized via short TEs.

If one shortens the waiting period to an intermediate point, the signal strength will be moderately reduced; however, the signal from areas with long T_1 will be more diminished than from areas with short T_1 . Thus, the image will reflect differences in T_1 values, so that the shorter the T_1 of a substance, the brighter it will appear on the image.

Finally, if the waiting period is very short, the pulses will be too close to each other to allow any significant recovery of longitudinal magnetization during the waiting period, so that signal strength is weak and the SNR ratio will be low. Thus, for T_1 weighting in SE sequences, the TR should be low—but not so low as to allow an insufficient time for magnetization T_1 recovery between pulses.

The difference in signal strength, as reflected by the separation between the curves of the various tissues in the previous example, constitutes the contrast in the image (see Figs. 2-7 and 2-8). Reference to the figures allows selection of an appropriate waiting time after the 90-degree pulse, at which one can obtain maximum separation between the curves and thus obtain maximum contrast between tissues in the MR image.

Because of differences in tissue composition (e.g., differences in proton density), in some circumstances the curves referred to previously do not follow the same contour but, instead, cross each other (Fig. 2-15). At such crossover points, there is no difference in perceived signal intensity, and thus the image will not show any contrast

Net z-axis Magnetization vs. Time

Figure 2-15. Recovery of z-axis magnetization for two substances with different proton density and T_1 . Note the crossover of signal difference, which results in contrast reversal.

between the two tissues. Gray matter and white matter in brain are examples of this crossover phenomenon, as a function of TR. Gray matter has a longer T_1 and a higher proton density than white matter. Thus, white matter exhibits rapid recovery of longitudinal magnetization (because of its short T_1) and appears brighter than gray matter. At a slightly longer pulse delay, the gray matter and the white matter become indistinguishable; at even longer recovery times, the gray matter achieves higher equilibrium magnetization and appears brighter than white matter in the image (see Fig. 2-11A-C).

For almost any two substances, an RF pulse sequence and TR can be selected to completely obscure any visible distinction between the two substances; however, imaging parameters that provide maximum contrast between tissues can also be found. However, maximum contrast is rarely obtained because other considerations (e.g., imaging time, slice coverage) cause compromises in one of the pulse sequence parameters so that "adequate versus optimal" contrast is obtained. In addition, the contrast observed on one side of the crossover point produces a different kind of contrast than on the other side. In similar fashion, a family of curves results as one plots transverse magnetization against time. The height of each curve is at peak amplitude initially and decays exponentially.

In spin-echo sequences, the longer the delay between the 90-degree and the 180-degree pulses, the more T_2 relaxation will have occurred and the less signal there will be to recover. The signal from substances with short T_2 values falls off more than from those with long T_2 values (see Fig. 2-7). Eventually, all signal disappears except for the signal from substances with long T_2 values. Thus, in a T_2 -weighted image, only substances with long T_2 values remain visible. Tissues with long T_2 values produce more signal than signals with short T_2 values.

Magnetic Resonance Angiography: Fundamentals and Techniques

E. Mark Haacke, Weili Lin

Magnetic resonance angiography (MRA) has become commonplace in the last few years.^{1, 23, 49} The improvements in pulse sequence design, hardware design, and postprocessing methods make it possible to acquire data in a short period with excellent vascular visualization in a variety of clinical applications. This chapter introduces the concepts behind MRA, the techniques used to obtain MRA studies, and its clinical applications.

Fundamentals of Imaging Gradient Echoes

The ability to collect an image with magnetic resonance is the result of the dependence of the frequency on the local field. This relationship is governed through the Larmor equation:

$$\omega = \gamma B_0 \quad (1)$$

where

ω = the angular frequency known as the Larmor frequency
 γ = the gyromagnetic ratio ($2\pi \times 42.6$ MHz/T)
 B_0 = the static magnetic field

For example, for a field strength of 1.5 Tesla (T), the Larmor frequency is equal to 64 MHz.

This frequency dependence is used to spatially discriminate information by applying a gradient field (G) throughout the region of interest in one or more directions. Now the frequency response is spatially dependent (Fig. 3-1):

$$\begin{aligned} \omega(x) &= \gamma B(x) \quad (2) \\ &= \gamma(B_0 + G \times x) \end{aligned}$$

If the signal is measured during the application of the gradient and subsequently Fourier transformed, the spectral amplitudes (the signal as a function of frequency) are obtained. This sampled signal is referred to as the *free induction decay* (FID) (Fig. 3-2).

The signal can also be obtained by using a bipolar gradient structure to create an echo (Fig. 3-3). However,

the bipolar gradient structure is able to give only one side of the frequency spectrum (either positive or negative frequency components), which, in theory (as in the FID case) is sufficient to reconstruct an image by taking advantage of the *hermitian symmetry* (see "Partial Fourier Imaging" later on) of the Fourier transform. In practice, it is not enough to reconstruct an image by using only one side of the frequency spectrum because of signal distortion caused by local field inhomogeneities. Therefore, the second lobe of this gradient structure is lengthened by a factor of two, so that both the positive and negative frequency spectra can be obtained. Using all the data gives a more robust image when the echo is not properly centered or when local gradients are present as a result of field inhomogeneities. Further, it also gives a $\sqrt{2}$ improvement in the signal-to-noise ratio (SNR).

Phase

Relative to the echo time, for a constant gradient, the phase as a function of time is determined from

Figure 3-1. In the presence of a gradient, the magnetic field has a linear dependence on position. The horizontal axis represents the position, and the vertical axis represents the magnetic field.

Figure 3-2. When a radiofrequency (RF) pulse is applied followed by a single-lobed gradient (G), a free induction decay (FID) of spins is formed. The time constant of the FID depends on the T2 of the material.

Figure 3-3. When a radiofrequency pulse is applied, followed by bipolar gradient structure, an echo is formed. At the echo the stationary tissue has accumulated a net phase of zero.

Figure 3-4. Phase behavior for stationary spins. Phase is a function of time, gradient strength, and location of spins. As shown, at $t = 0$ an echo is formed and the phase of stationary spins is zero. Here we assume x is nonzero.

Figure 3-5. A, Pictorial representation of the phase for stationary and constant velocity spins as a function of time when a bipolar gradient structure is used. B and C, Graphical and vector representations of the phase, respectively. The solid line is for stationary spins, and the dotted line is for constant velocity spins. ϕ indicates the phase shift of constant moving spins at the echo.

$$\phi(t) = \omega t = \gamma G x t \quad (3a)$$

As shown in Figure 3-4, the phase is a function of time and gradient strength. Since $G_1 = G$, $G_2 = -G$ and $t_1 = t_2$, equation 3a can be rewritten as

$$\phi(t) = \gamma x (G_1 t_1 + G_2 t_2) = 0 \quad (3b)$$

Therefore, the accumulated phase at the echo is always zero for these bipolar gradient structures (Fig. 3-5).

For stationary spins, the phase is generally determined from

$$\phi(t) = \gamma x \int G(t) dt \quad (4)$$

Figure 3-5B shows a linear growth in phase during the dephase portion of the gradient and a linear decrease in phase after the gradient is reversed for stationary tissues. No change in phase occurs when there is no gradient on.

The velocity phase behavior is quadratic and overshoots the zero phase mark at the echo.

T2* Dephasing

In the presence of a local field inhomogeneity, the effective decay of the signal is quickened, and T_2^* is modified as

$$R_2^* = R_2 + \gamma \Delta B \quad (5)$$

where $R_2^* = 1/T_2^*$ and $R_2 = 1/T_2$ where T_2 is the T_2 value when no field inhomogeneities (ΔB) are present. This can be qualitatively understood, since the spins “see” different fields and become out of phase. If the time of the echo is calculated locally, it is discovered that it has shifted away from the center. The farther the echo shifts, the less signal remains in the sampling window (Fig. 3-6).

Chemical Shift

The presence of local field variations causes a shift in the frequency for different molecules. Lipids, for example, precess at a frequency (Δf), 3.35 parts per million (ppm)

Figure 3-6. Local field inhomogeneities introduce a shift of the location of the echo. A, A two-lobed gradient structure is shown with an echo at the center of the second lobe (TE1); therefore, the signal is symmetrical. The gray indicates the area under the gradient from local field inhomogeneities. B, The location of the echo is shifted to the left (TE2) compared with A, and the signal becomes asymmetrical. If the shift is large enough, it will cause significant signal loss.

Figure 3-7. When a voxel contains water (20%) and lipid (80%) components, the signal intensity of the voxel is a function of echo time (TE). As shown in the plot, the signal intensity is modulated by a sinusoidal function with a period of 224 Hz (3.35 parts per million at 1.5 T). The spin-echo behavior is shown in A, and gradient field echo (GFE) behavior is shown in B. A T1 of 950 msec, T2 of 100 msec, and T2* of 50 msec (gray matter) are used as water relaxation parameters and T1/T2/T2* = 250/80/10 msec (fat) are used as lipid relaxation parameters. The signal behavior for a fat and water voxel is further modulated by an exponential decay (T2*). The frequency of modulation appears to be doubled at the lower values of TE because fat overwhelms the water and creates a negative signal, which is then made positive by taking the magnitude of the image. SE, spin echo.

lower than that for water. They therefore have a different phase development as a function of time and at the echo will not necessarily be in phase with water. When a voxel contains fat and water components, the signal intensity of this voxel depends on the echo time (TE) used (Fig. 3-7). At 1.5 T, for a voxel containing 50% each of water and fat, the signal intensity of this voxel will be one unit when TE = 4.5 msec (since fat and water are in phase so that the total signal is the sum of both components) and zero when TE = 6.7 msec (since fat and water are out of phase, and signal intensity is the absolute difference between these two components). To see this, note that the phase difference between the two is $\gamma\Delta BTE$, which is 2π at 4.5 msec and 3π at 6.7 msec. Consequently, the opposed phase nature can be used to suppress fat signal.^{27, 60}

Resolution

The data are sampled in the read direction over n points. If the field of view (FOV) is defined as L , the resolution in the image will be (at best) L/n , or

$$\Delta x = L/n \quad (6)$$

For example, if the carotid vessel is being imaged, its lumen is 10 mm before the bifurcation and the magnetic resonance imaging (MRI) resolution is 1 mm, the smallest percentage of stenosis that can be measured is 100/10%. To detect a high percentage of stenosis, the resolution of images must be improved.

Clearly, high-resolution imaging plays an important role in MRA.^{25, 37-39, 56} First, it can be used to reduce flow-related artifacts through the reduction of the intravoxel dephasing.^{25, 37, 56} Second, it is able to improve the visibility

of the vascular system^{37, 38} (Fig. 3-8). This is especially true for the peripheral vascular system and stenotic regions. Third, the partial volume artifacts can be reduced, and hence vascular contrast is improved (Fig. 3-9). However, there are two major disadvantages associated with high-resolution imaging methods. The SNR will be reduced because of the smaller voxel size, and the minimum repetition time (TR) will be increased because the number of sampling points is increased. Therefore, when the SNR is poor, more acquisitions may be needed to compensate for the SNR lost.

Contrast

The main strength underlying the success of MRI studies is the soft tissue contrast. *Contrast* is defined as the signal difference between two tissues. *Relative contrast* is the signal difference normalized to the signal of one of the two signals. The contrast is the result of the tissue properties ρ , T1, and T2. Blood flow adds another variable to the calculation of contrast. Consider a simple imaging experiment with a very short TE and a long TR relative to the T1 values of all tissues. In this case, contrast is determined solely by spin density (Fig. 3-10). As TR is shortened to on the order of the T1 of a tissue, the image becomes T1-weighted (Fig. 3-11). For gradient-echo sequences, the TR can be shortened much below T1 and the radiofrequency (RF) pulse reduced to an angle well under 90 degrees. For no transverse magnetization before any RF pulse and after equilibrium has been reached, the signal as a function of flip angle (θ) can be expressed as

$$s(\theta) = \frac{\rho \sin \theta (1 - E_1)}{1 - E_1 \cos \theta} \quad (7)$$

Figure 3-8. Comparison of vascular visibility when different matrix sizes are used. The field of view was kept constant for this comparison. The matrix sizes used were 128×256 (A), 256×256 (B), and 512×256 (C), respectively. When the in-plane resolution is improved, more peripheral vessels can be seen in the images. However, the signal-to-noise ratio is reduced accordingly. The 512 image has little stair-step artifact, although it does suffer a DC bright line artifact in the center of the image (arrow).

where ρ is the effective spin density and $E1 = \exp(-TR/T1)$.

The response as a function of flip angle shows why an intermediate flip angle between 0 and 90 degrees gives the best signal. The peak signal occurs when $\cos \theta = E1$; this is referred to as the *Ernst angle* (Fig. 3-12).

Two-Dimensional and Three-Dimensional Imaging

Two-dimensional (2D) and three-dimensional (3D) images can be obtained by adding a phase-encoding gradient table in each remaining direction to be imaged. The resolu-

tion in each phase-encoding direction is the FOV divided by the number of phase-encoding steps, as

$$\Delta y = L_y/n_y \quad (8)$$

for the in-plane phase encoding or

$$\Delta z = L_z/n_z \quad (9)$$

for the through-plane phase encoding (also referred to as *partition encoding*). In general, the 3D imaging method is preferable when a thinner slice is desired and flow velocity is high enough so that the flow saturation problem is not significant. Moreover, 3D imaging methods have a better SNR and are less sensitive to field inhomogeneities than

Figure 3-9. Comparison of vascular contrast when a different slice thickness was used to acquire images. A maximal intensity projection (MIP) was used to create axial projection images. The coverage of all three MIPs was kept the same, but with a slice thickness of 2 mm (A), 1.5 mm (B), and 1 mm (C). Since the thinner slice was used, the vascular contrast was improved because of the reduction of partial volume effects.

2D imaging methods. This is easily understood from two perspectives. First, the smaller the voxel size, the less dephasing is across a pixel, since the phase error (e.g., that caused by field inhomogeneity $\phi = \gamma \Delta BTE$) is invariant spatially as the imaging parameters are changed. If there is a 2π phase variation across a voxel, this would cause complete signal loss for a uniform distribution of spins (Fig. 3-13A). However, for twice the resolution, the phase variation is cut in half, being 0 to π in the first, smaller voxel and π to 2π in the second voxel (Fig. 3-13B). The conventional sequence diagrams for both 2D and 3D acquisition methods are shown in Figure 3-14. The phase encoding in the slice select direction is often referred to as the *partition encoding*, a term we will use here. The field-echo time (FE) refers to the time from the beginning of the gradient structure to the echo along the read direction.

The echo time refers to the time from the center of the RF pulse to the echo.

Fundamentals of Flow Effects

Effects of Motion on the Phase

The previous discussion of phase needs to be modified when a spin moves. As an example, consider just the simple case of constant velocity moving spins:

$$x(t) = x_0 + vt \quad (10)$$

where x_0 , v , and t represent the initial position of the spins, constant velocity, and time, respectively.

Figure 3-10. Spin-density image of the head acquired with a 5-degree flip angle (Figure 3-11 provides imaging parameters). Because blood vessels sit in gray matter (GM) and GM and blood have the same spin density, it is not possible to distinguish between the two. The sagittal sinus (*arrow*) is saturated and isointense with GM.

Figure 3-11. T1-weighted image of the head for (A) 15 degrees and (B) 30 degrees. Since the T1 of blood is longer than that of gray matter, it appears darker if it is saturated but may appear isointense if some inflow effect remains. Imaging parameters: TR = 40 msec, TE = 8 msec; 64 partitions, 2-mm slice thickness; matrix size, 256 × 256.

In-Flow Effects

Figure 3-12. Signal intensity as a function of flip angle (see Equation 7 in text). A TR of 35 msec is used with T₁ of blood equal to 1200 msec and gray matter (GM) equal to 950 msec. The *solid line* indicates the ideal case that blood experiences only one ($N = 1$) radiofrequency (RF) pulse. In contrast, when blood experiences more RF pulses, as when $N = 5$ (*line of circles*), $N = 10$ (*line of squares*), or $N = 20$ (*line of diamonds*), the signal of blood is reduced. The signal behavior of GM is also plotted (*long dashed line*). As shown, the blood may become isointense with GM at 15 degrees when N is greater than 10 and less than 20.

Figure 3-13. A, Pictorial representation of intravoxel dephasing. When a larger pixel is used, the integration of spins from 0 to 2π will give a zero signal (0). In contrast, when the resolution is reduced by a factor of 2, the integration of spins will be from 0 to π for the first pixel and π to 2π for the second pixel (*B*) and little signal loss occurs (see Table 3-1).

Figure 3-14. Sequence diagrams of both 2D (*A*) and 3D (*B*) sequences. The only difference between these two sequences is in the slice select direction. For the 3D sequence, an extra phase table (*dashed line*) is added to encode information along the slice select direction.

The phase during sampling is found from the expression

$$\phi(t) = \gamma \int G(t)x(t)dt \quad (11)$$

For a simple bipolar pulse as shown in Figure 3-5, the phase at the echo is

$$\phi(t) = \gamma v G(t) t_1^2 \quad (12)$$

This simple dependence of the phase on velocity is the fundamental behavior from which many MRA concepts can be understood.

Dephasing

For plug flow, all spins move in the same direction at the same speed independent of the location of the spins with respect to the vessel wall. When all the spins within a voxel are added together, they add coherently and the final signal has the same phase. In contrast, for laminar flow, the velocity of spins is dependent on the location with respect to the vessel wall (Fig. 3-15). The spins at the center of the vessel have the highest speed, and those at the edge of the vessel have the lowest. Consequently, a velocity distribution inside a given voxel causes a different phase shift for each isochromat of spins inside the voxel. The total signal in one voxel is obtained from an integration of the local signal across the entire voxel.

When the total phase shift across a voxel is uniformly distributed from 0 to 2π , there will be complete signal dropout. This phenomenon is known as *flow dephasing* or *flow void*. It usually can be seen in stenotic regions or tortuous vessels when insufficient motion compensation is used. For example, in the regions of the carotid bulb and poststenosis, a secondary flow or vortex flow is normally seen. This flow pattern also introduces signal loss (Fig. 3-16).

Table 3-1 shows the relationship between the degree of dephasing and the remaining signal.

Figure 3-15. Laminar flow pattern inside a blood vessel. Because flow velocity is location-dependent, the spins have a non-uniform distribution compared with that of plug flow. As shown, the voxel close to the center of the vessel has more uniform spin distribution compared with that at the edge of the vessel. This nonuniform spread in velocity can lead to spin dephasing.

Figure 3-16. A, The same concept as in Figure 3-15 also holds for poststenosis regions, where secondary flow develops inside an aneurysm or beyond an aneurysm. B, In the region of the carotid bulb, a secondary flow pattern is normally seen because of the pressure gradient change. This causes flow dephasing as well as saturation and results in signal void in this part of the blood vessel.

Compensating Moving Spins

To eliminate or reduce the problems associated with spin dephasing, a short echo time can be used.^{32, 39, 54} Alternatively, a velocity compensation gradient structure can be used.^{24, 34, 44} It is possible to keep both stationary and moving spins in phase at the echo. This is accomplished by adding a third gradient lobe to the original gradient structures so that the total area still adds to zero, and the stationary spins are therefore still rephased, while the first moment of the phase is also zero for any speed. Expressed mathematically, the following conditions are applied:

$$\gamma x \int G(t)dt = 0 \quad (13)$$

and

$$\gamma v \int G(t)tdt = 0 \quad (14)$$

To compensate constant acceleration spins, four lobes are required to give three degrees of freedom so that stationary spins, constant velocity spins, and acceleration spins can all have a zero phase at the echo. The tradeoff by using a four-lobed gradient structure is that the echo time will be increased. This can cause some spin dephasing problems when higher-order motion effects are present, such as in secondary or disturbed flow, or for tortuous flow, such as in the carotid syphon.

Table 3-1. Relationship Between Degree of Dephasing and Remaining Signal

$\Delta\phi$	S/S_0
2π	0
$3\pi/2$	$2\sqrt{2}/3\pi$
π	$2/\pi$
$\pi/2$	$2\sqrt{2}/\pi$

Figure 3-17. A, Image of the neck acquired by a 2D sequence with a flip angle of 90 degrees. Because of the pulsatility of blood flow, ghosting artifacts are seen along the phase-encoding direction (y-axis). B, When the flip angle was decreased to 20 degrees with the same sequence, the signal intensity of the “ghosts” was decreased.

Higher-Order Terms

Even with velocity compensation, higher-order motion effects can still be seen in tortuous or stenotic flow. For the same bipolar gradient structure, acceleration compensation varies as FE^3 or as FE^2 if constant velocity spins are compensated.

Ghosting Artifacts

Ghosting artifacts are commonly seen in MRI studies. Two reasons can account for this type of artifact. First, uncompensated (or pulsatility of) moving blood causes the duplication of the blood vessels along the phase-encoding direction. The locations of the ghosting depend on the cardiac cycle and TR. This phenomenon is usually seen in peripheral MRA studies (i.e., of the legs) because of the high degree of pulsatility. When a large flip angle is used, the signal intensity of the ghosting artifacts will be significant (Fig. 3-17).

On the other hand, physiologic motion such as eye or cerebrospinal fluid (CSF) movement can also cause ghosting along the phase-encoding direction. To avoid having “ghosts” obscure other structures, the frequency and phase-encoding directions are usually swapped before any data acquisition so that the direction of ghosting becomes horizontal instead of vertical.

Inflow

Given that all spins are now rephasing at TE, any velocity profile can be imaged. The main effect of obtaining a blood signal comes from the fact that inflowing blood has experienced fewer RF pulses and has more signal than tissue with similar T1 values, which experience many

RF pulses and is essentially saturated (Fig. 3-18). This phenomenon is well known as flow enhancement or an inflow effect. The MRA imaging method based on this concept is called time-of-flight (TOF) MRA to differentiate it from the phase-contrast (PC) method (see later), which uses the phase shift introduced by moving spins.

Saturation

The inflow effect makes it possible to obtain good contrast between vessels and stationary tissue because the stationary tissue experiences more RF pulses and eventu-

Figure 3-18. For through-plane flow with a laminar flow profile, blood will have higher signal at the entry region (slice 1) when compared with the region where blood flows deep into the slab. Numbers represent slice numbers.

ally the magnetization becomes saturated. Consequently, when the velocity of blood in a vessel is slow, both background tissue and blood magnetization are saturated; hence blood vessels become isointense to the stationary tissue. This is usually the case in the head because gray matter (GM) and blood have similar spin densities and T1 values. In addition, this problem is seen more in 3D TOF imaging methods, since a larger imaging volume is normally acquired.^{26, 41}

Saturation Pulses

It is also possible to apply another RF pulse just before the usually low flip angle pulse to saturate the signal from stationary tissue and see fresh blood flow into this saturated band. Flow that takes place between the saturation pulse and the echo time can be seen as bright in the saturated band. This band can also be applied parallel to the usual 3D slice select direction, but offset from it, to saturate spins coming from one side of the slab to be imaged. An example is shown in Figure 3–19, in which a saturation pulse was used to saturate the venous blood magnetization and only the arteries were seen in the image (Fig. 3–19B).

Phase Contrast

One way to eliminate the problems associated with flow saturation is to obtain flow information by collecting two images, each of which is not perfectly compensated in one direction so that a phase shift exists at the echo along the uncompensated direction, which is different for the two sequences.^{14, 15} This is the primary difference between PC methods and TOF MRA. Subtracting one image from the next eliminates the background. This can be done with the complex data or the phase images themselves. The sequence diagram of an interleaved PC method is shown in

Figure 3–20. This method has the advantage that when saturation is a problem (as it is for slow flow), the background is easily removed. The resulting phase images contain values only from $-\pi$ to π as long as the peak velocity is such that $|\phi(v)| < \pi$. The velocity at which $|\phi(v)| = \pi$ is referred to as the *velocity-encoding value* (VENC).

Unfortunately, several disadvantages are associated with PC methods, which require at least four separated scans to extract flow in all three directions yet given the very short TR values that can be used, rapid acquisition of data is still possible. Because subtraction is used to remove the background signal and extract flow information from four scans, patient motion must be avoided. Eddy currents also affect the phase behavior in the images. Moreover, this method requires a choice of the maximum velocity so that aliasing will not occur in the phase images. One way to overcome the problem of the correct choice for the VENC is to use a multiple VENC in one sequence so that a wide range of velocity information can be obtained.

Finally, this method, like TOF methods, is apt to suffer from spin dephasing because of the rapid flow. A shorter TE is necessary for PC methods as well. The TOF and PC methods are likely to complement each other in the future.

Projection Images

The use of 2D TOF over thick slices is often referred to as projection imaging because of the projection of information over the slice thickness. In these methods, excellent background suppression is required. Interleaved 2D PC is the method of choice when rapid imaging is required.

Sequence Parameters

As mentioned earlier, 2D and 3D imaging methods have different advantages and disadvantages and are suitable for

Figure 3–19. Images acquired with a conventional 2D sequence in the region of the neck. *A*, When saturation was not used, both arteries and veins were seen in the image. *B*, In contrast, when a saturation pulse was placed above the image slice, the veins were saturated and only arteries were seen in the image.

Figure 3-20. Sequence diagram for an interleaved phase contrast acquisition method. A flow-encoding gradient (bipolar gradient) shown in gray was placed along the slice select direction. As shown, the sign of this flow-encoding gradient was reversed for the second part of the data acquisition when compared with the first part. Because an interleaved data acquisition method was used, the effective TR was increased by a factor of 2. Slice select (SS), phase-encoding (PE), frequency-encoding (FE) directions; and analog-to-digital converter (ADC). RF, radiofrequency.

different applications. Consequently, the imaging parameters for 2D and 3D imaging methods are different to optimize vascular contrast.

Two-Dimensional Imaging

In general, 2D imaging is used to image slow flow because this method is less sensitive to flow saturation. Moreover, 2D imaging is also suitable for dynamic studies because of its short data acquisition time. Unfortunately, 2D imaging is highly sensitive to local field inhomogeneities. It is also more difficult to achieve high resolution along the slice select direction compared with 3D imaging.

Three-Dimensional Imaging

In contrast to 2D imaging, 3D acquisition is used to cover a large region of interest and to achieve high resolution along the slice select direction. Moreover, the SNR is normally higher than in 2D imaging because more points are acquired along the slice select direction. However, 3D TOF suffers from flow saturation effects when a large volume is covered or when slow flow is present. As discussed previously, 3D PC is less affected. General advantages of 2D versus 3D imaging are shown in Table 3-2.

Technical Developments in MRA Sequences

Saving Time

Once a good MRA scan has been collected, one can look at methods to speed up its acquisition. This will invariably mean a loss of SNR, given that resolution remains the same.

Rectangular Field of View

A simple trick is to reduce the number of phase-encoding steps while decreasing the FOV in the phase-encoding direction. For example, reducing the number of steps from 256 to 128 and reducing the FOV from 256 to 128 mm maintain the resolution, cut the imaging time in half, but reduce the SNR by a factor of $\sqrt{2}$. For imaging a child's head, this is possible; for adults, however, the reduction is usually to 192 steps—still giving a considerable savings in time of 25%. When nonintegral ratios between the original FOV and the reduced FOV are used, a careful interpolation algorithm must be employed to retain the correct aspect ratio of images. Figure 3-21 shows a comparison with (Fig. 3-21A) and without (Fig. 3-21B) the use of rectangular FOV.

Partial Fourier Imaging

Use in the Phase-Encoding Direction. There is a special symmetry property of the Fourier transform for a real object that makes it possible to design a data collection

Table 3-2. Comparison of Two-Dimensional (2D) and Three-Dimensional (3D) Imaging

2D		3D	
Advantages	Disadvantages	Advantages	Disadvantages
Faster	Thicker slice	Thinner slices	Slower
Better inflow	More T2* loss	Less T2* loss	Blood saturation
High CNR	Low SNR	High SNR	Low CNR

CNR, contrast-to-noise ratio; SNR, signal-to-noise ratio.

Figure 3-21. A, Image acquired with a conventional 3D sequence in the region of the neck. The imaging parameters are TR, 35 msec; TE, 8 msec; flip angle, 15 degrees; and matrix size, 256×256 . The total data acquisition time is about 10 minutes. B, The same imaging parameters are used, except that the matrix is reduced to 160×256 and the rectangular field of view (FOV) is used to acquire the image. Although the signal-to-noise ratio (SNR) is reduced accordingly, the total data acquisition time is reduced to 7 minutes. C, At this stage, data in the neck are often collected with a 256×512 acquisition. Although this image was not obtained using a reduced FOV, the SNR is sufficient that it would be possible to do so if the carotid bifurcation were the region of interest.

method that in theory saves a factor of 2 in data collection time. This property, known as *hermitian symmetry*, relates the negative data to the positive data so that only the positive data, for example, need be collected and the negative data will be recreated from it. The expression is simply

$$s(-k) = s^*(k) \quad (15)$$

where

k represents the phase-encoding value
 $s(k)$ is the signal

In practice, more than half the data is collected and special algorithms are used to reconstruct the data (Fig. 3-22). Once again, a factor of nearly $\sqrt{2}$ is lost in SNR.²⁵ A comparison is shown in Figure 3-23 to demonstrate the partial Fourier reconstruction method.

Use in the Read Direction. This trick can also be used to reduce the echo time by putting the echo off center with respect to the data sampling window²⁵ (Fig. 3-24). This reduced echo time allows better suppression of the dephasing of moving spins from higher-order motion. For example, a 25% asymmetrical echo with 256 sampling points indicates 64 points before the echo and 192 points collected after the echo. Mathematically it represents a symmetrical echo multiplied by a rectangular pulse in the time domain, and it translates to a convolution of the ideal image with a complex filter function. This reduces the sharpness of the

reconstructed image. Therefore, the half-Fourier reconstruction is necessary to eliminate this artifact. Figure 3-25 shows sequence diagrams of the TE = 5.1 msec sequence (even shorter echo times are available today).

To achieve high resolution, longer echo times may have to be used because of the limitation of the maximum gradient strength in the system. Consequently, the longer echo time would increase the flow-related artifact since the higher-order motion-dephasing effects increased. Alternatively, an off-center echo can be used such as 6.25%, 12.5%, or 25%, and the echo time decreases accordingly.

Overcoming Saturation Effects

Two solutions can be used to reduce the saturation problems associated with 3D TOF imaging methods: (1) increase the blood signal, and/or (2) reduce the background tissue signal so that the contrast between blood vessels and background tissue can be improved. Alternatively, post-processing methods can be used to remove unwanted tissue structures (see "Processing and Image Display").

Increasing Signal from Blood

Central k -Space Reordering. In certain sequences, there is a wait time (TW) between application of the partition and phase-encoding loops. In this case, central reordering collects the largest signal at the lowest values

Figure 3-22. Pictorial representation of k-space coverage. Instead of collecting the entire k-space, only three fourths of the k-space was acquired along the read direction. A partial Fourier reconstruction was used to recover the lost information without blurring the image. The shaded portion represents the data used for the partial Fourier reconstruction, and the entire figure represents the data collected from the imager (A). B, After reconstruction, data space is symmetrically covered. The data are collected with m points before the echo and P points after the echo, with $m + P - 1 = 2n$.

of the k-space or at the low spatial frequency values (Fig. 3-26). This enhances the signal not only from the fast blood but also from any blood that has this TW to regrow. In addition, when a $T1$ reduction contrast agent such as gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA) is administered, the centric reordered k-space scheme can be used to further improve the vascular contrast, since the half-life of Gd-DTPA is short and Gd-DTPA is most effective immediately after the injection of contrast agents.

Variable Flip Angle as a Function of Radiofrequency Pulse Number. Signal can also be enhanced by not applying a constant RF pulse angle every time. A constant RF pulse usually leads to saturation of the signal (it always does for stationary tissue if the angle is greater than the Ernst angle). If the flip angle is varied to give constant transverse magnetization each time the RF pulse is applied, the signal can be enhanced (even specifically at low k-space if desired).

Contrast Agents. One of the main difficulties associated with 3D TOF MRA studies is the saturation of slow flow. To reduce the saturation problem, a thinner 3D slab can be used so that more fresh blood can flow into the imaging volume.^{6, 7, 45} However, this method requires several overlapping thin slabs to cover the region of interest, and

cooperation of the patient is required. Alternatively, a contrast agent, Gd-DTPA, may be used to shorten the $T1$ over reasonably long periods^{9, 11, 38} (its half-life in the blood is about 12 minutes). For example, when a high dose of Gd-DTPA is used, the $T1$ of blood may be reduced by a factor of 4 and the contrast between blood and stationary tissue will be substantially increased (Fig. 3-27). An example of preadministration and postadministration Gd-DTPA is shown in Figure 3-28. As expected, after injection (Fig. 3-28B), more small vessels are seen as compared with Figure 3-28A. It can also be used to see $T2^*$ effects during the first minute of its application, after which its concentration is so low that $T2^*$ effects disappear.

Multiple Thin-Slab Acquisition. Multiple thin-slab acquisition methods can also be used to reduce spin saturation problems because spins experience fewer RF pulses compared with single thick-slab acquisition methods (Fig. 3-29). Consequently, the region of coverage is reduced accordingly. To cover a large region of interest, several thin slabs with 25% to 50% overlap can be used. Better-quality images in the regions of overlap and in the rest of the images can then be combined using maximum intensity projection (MIP) processing to generate the projection images (see later).

Figure 3-23. A, Image collected with 64 points before the echo and 192 points after. It is zero filled in-plane to 512 and then reconstructed with a 2D fast Fourier transform to create a 512×512 image. B, The image was reconstructed using 64 points before and 192 points after the echo with the partial Fourier reconstruction method to create an equivalent 384 points along the read direction and zero filled to make 512×512 images. C, The image was collected with 64 points before the echo and 448 points after, with 512 phase-encoding steps to create 512×512 images. Note the improved resolution and loss of signal-to-noise ratio compared with B. Even the 512×512 acquisition with the conventional reconstruction does not lose the same vessel sharpness. (Courtesy of Ramesh Venkatesan, B. S., Case Western Reserve University, Cleveland, Ohio.)

Improving Background Tissue Suppression

Too high a signal from background obscures the blood vessels. By reducing background signal, the vessels become more visible.

Spatially Variable Flip Angle or TONE Pulses. One method of keeping the signal uniform in response across the FOV in the slice select direction (for blood flow perpendicular to the imaging plane—that is, in the slice select direction) is to vary the flip angle spatially (Fig. 3-30). Using small flip angles and increasing to large flip angles keep inflowing blood fairly uniform as it passes through the volume.³⁵ The principle is the same as that previously described, but it is accomplished by appropriately redesigning the RF pulse to accomplish the desired shape of the RF response. This is most often useful in neck studies (Fig. 3-31).

Magnetization Transfer Saturation. Bound macromolecules have very short T2 values (<1 msec), whereas more mobile protons have much longer values (50 to 100 msec). Through a cross-relaxation mechanism, the latter exchange with the former and are dephased as a result of the local field environment. By exciting a pulse at an off-resonance value of roughly 2 kHz, those water-like tissues with a long T1 are saturated and do not contribute to the signal.^{13, 62} Gray matter is affected less than white matter, but the effect is still large enough that up to a 40% drop in brain parenchyma signal has been seen.⁶³ This makes the vessels much easier to visualize because the partial-volume artifact is reduced. In practice, a frequency offset saturation pulse can be applied to suppress background tissue with negligible effect on the moving blood by an optimal choice of offset frequency and bandwidth of the saturation pulse.^{16, 48}

SYMMETRIC ECHO

ASYMMETRIC ECHO

Figure 3-24. Pictorial representation of a symmetrical and an asymmetrical echo along the frequency-encoding direction. In this manner, the frequency encoding (FE) can be reduced substantially. Here the FE is defined as the duration from the beginning of the gradient to the echo.

Figure 3-25. Sequence diagram of $TE = 5.1$ msec, which has an asymmetrical echo of 12.5% of the entire sampling window. The sequence is velocity compensated along the frequency-encoding and slice select directions. The slice select direction is also phase-encoded, and this encoding is usually referred to as “partition” encoding to distinguish it from “in-plane phase” encoding. (Courtesy Dee Wu, Ph.D., Case Western Reserve University, Cleveland, Ohio.)

Sequence Diagram

Figure 3-26. Two different methods are used to cover the k-space: sequential (A) and centric (B). For the sequential order, either the positive or negative high-frequency components are collected first and then the lower-frequency components. The gray-scale levels indicate the time during which the data are collected. The darker the color, the later the data are collected. For centric ordering, the low-frequency components are collected before the high-frequency components.

Figure 3-27. When a T1 reduction contrast agent is used, such as gadolinium-DTPA, the T1 of the blood will be reduced dramatically immediately after the injection. Here a T1 of 300 msec is used to create this plot. This plot is analogous to that in Figure 3-12. The solid line indicates that the blood experiences only one radiofrequency (RF) pulse ($N = 1$); the line of circles plots data for $N = 5$; the line of squares, for $N = 10$; and the line of diamonds, for $N = 20$, and the dashed line represents gray matter (GM). Even when blood experiences 20 RF pulses, the contrast between blood vessel and GM remains high.

Figure 3-28. Comparison without (A) and with (B) the injection of gadolinium (Gd)-DTPA. When Gd-DTPA is used, more small vessels are seen than without injection. However, more enhanced veins are also seen in the image, which tends to obscure vessels in the maximum intensity projection images. The imaging parameters were TR = 35 msec, TE = 8 msec, 64 partitions, slab thickness 70 mm, and matrix size 256 × 512 (phase by read).

Figure 3-29. Lateral view of intracranial vessels. Images were acquired with a TE of 6.5 msec and 64 slices per slab. Two slabs with 50% overlap were combined to create the maximum intensity projection images. A large region of interest was covered without the problem of spin saturation.

Figure 3-30. A pictorial representation of the flip angle along the slice select direction as it is varied spatially. The slope of this TONE pulse can be chosen according to the flow velocity to optimize response along the slice select direction. If the arterial flow (*dashed line*) is up, the solid line would be used to optimize arterial blood signal uniformity. RF, radiofrequency.

This contrast enhancement is especially helpful for visualizing slow flow in the regions of peripheral vessels as well as aneurysms³⁹ (Fig. 3-32).

Several problems are associated with this method:

1. The power deposited may be high.
2. The saturation pulse may also saturate the moving spins because of the local field change.
3. This saturation will have no effect on the fatty tissue; hence, fatty tissue will appear relatively bright compared with the background.

To overcome the problem associated with the specific absorption rate (SAR) limit, a double side band saturation pulse can be applied to achieve the same effect as that of a single side band but with half of the SAR. Moreover, a temporal variable saturation pulse can be applied so that a large saturation pulse is applied when the low spatial frequency components are collected to suppress most of the background tissue. However, a smaller saturation pulse can then be applied for the high-frequency portion. In this way, the total SAR can be reduced and yet have the same effect as that of a constant saturation pulse.⁵⁸ On the other hand, a frequency-selective fat saturation pulse can be used to suppress the unwanted fat signal³⁹ (see Fig. 3-32).

Fat Saturation. As mentioned earlier, fat and water have different resonant frequencies. When a frequency-selective, small bandwidth saturation pulse centered on the fat resonant frequency is used, it should be possible to suppress fat signal without affecting the water signal.^{12,31} Because of the nonuniform static field, it is difficult to

obtain uniform fat suppression throughout the entire imaging volume. Moreover, the choice of offset frequency and bandwidth of the fat saturation pulse requires fine-tuning so that the best combination of the parameters can be obtained.

A sequence diagram is shown in Figure 3-33. A frequency-selective fat saturation RF pulse is applied outside of the normal 3D encoding direction so that the fat saturation is applied only once every 3D encoding loop. Because the fat signal will be at a minimum immediately after the application of the fat saturation pulse, a centric reordering along the slice select direction is used so that the low-frequency component will be collected while the fat signal is at a minimum³⁹ (Fig. 3-32C).

Alternate Imaging Schemes

TOF bright blood imaging is not the only way to collect angiographic information. Bright blood techniques and PC techniques have been discussed; here we consider three other possible methods.

Black Blood

There are at least six ways to get blood to appear dark in an MRA study:

1. If the blood is not motion compensated and flow is fast enough, the signal within a voxel with a gradient large enough to create a 2π phase change across the voxel will vanish.

Figure 3-31. Conventional 3D MRA study with a constant radiofrequency pulse (A) versus a caudal to cranial increase in flip angle spatially (B). Note the more uniform response along the slice selection direction when the latter, TONE, pulse is used.

Figure 3-32. Comparison without (A) and with (B) the use of magnetization transfer saturation (MTS) pulse. The MTS pulse used here has an offset frequency at 1.5 kHz and a bandwidth of 250 Hz. The total duration time of this pulse was about 8 msec. When the MTS pulse is used, more small vessels are seen. However, the fat also becomes apparently brighter because the MTS pulse has no effect on the fatty tissue. C, When a frequency-selective fat saturation pulse is used outside the 3D loop, the fat signal is suppressed substantially. (From Lin W, Tkach JA, Haacke EM, et al: Intracranial MR angiography: Application of magnetization transfer contrast and fat saturation to short gradient-echo, velocity-compensated sequences. *Radiology* 186: 753-761, 1993.)

2. Saturation can be used to suppress the signal from the blood before it enters the imaging volume.
3. A π pulse can be used to invert the spins from blood and the signal acquired at the null point of blood (Fig. 3-34).
4. A flow-sensitive fast-imaging method can be used.
5. The old-fashioned signal void can be created by letting blood flow out of a slice between a $\pi/2$ pulse and a π pulse of a spin-echo acquisition.
6. A T2* contrast agent can be used to dephase the signal from blood.

The primary advantage of using black blood acquisition methods is to reduce the problems associated with higher-order motion artifacts (spin dephasing)^{17,18} since all the blood vessels will appear dark. However, this method requires special postprocessing methods so that blood vessels can be separated from other low signal intensity structures such as sinuses.

Steady-State Free Precession Bright Blood

Steady-state free precession imaging can also play a role in bright blood MRA studies. For tissue with small T1/T2 ratios and large flip angle, short TR scans can give high SNR. Blood has a T1/T2 ratio of about 6, which is small enough that at a large flip angle it will have significantly brighter signal than that of the surrounding muscle or brain parenchyma.⁴⁹

Spin-Density Approach

Fast imaging can also be used to highlight spin-density differences.⁴⁹ Blood has an effective spin density (i.e., spin density weighted by T2*) higher than all of muscle, fat, or brain parenchyma. Therefore, using a low flip angle (much less than the Ernst angle) can bring about excellent contrast even if the blood is not flowing (i.e., this would be good for obstructed flow studies).

Figure 3-33. Sequence diagram showing the use of magnetization transfer saturation (MTS) and fat saturation (FS) pulses. The fat saturation pulse is applied outside the 3D loop so that it will be applied only once for one step of the 3D encoding procedure (including slice select [SS], read [R], and phase-encoding [PE] gradient timings). To acquire the data when the fat signal is at a minimum, a centric reordering scheme is used along the SS direction so that the low-frequency components are collected before the high-frequency components. There is a delay time (TW) between the end of one 3D encoding and the next phase-encoding step to apply the MTC and FS pulses and adjust contrast as desired. (From Lin W, Tkach JA, Haacke EM, et al: Intracranial MR angiography: Application of magnetization transfer contrast and fat saturation to short gradient-echo, velocity-compensated sequences. *Radiology* 186:753-761, 1993.)

Flow Quantification

PC methods can be used in a cine format to generate information on the flow rates throughout the cardiac cycle in just a few minutes. A variety of methods exist to do this, including a one-dimensional (1D) method called real-time acquisition and velocity evaluation (RACE), a 2D cine phase method, and a 1D or 2D projective Fourier

Figure 3-34. By applying an extra nonselective π pulse before collecting the data, followed by a selective π pulse to invert the spins in the volume to be imaged, a delay time of T_1 is used to null inflowing blood while leaving stationary tissue bright. This is demonstrated in the heart from a single partition (1 of 16 collected) of 2.5-mm thickness. Note the bright wall of the aorta and myocardium. (Courtesy of Debiao Li, Ph.D., Washington University, St. Louis.)

phase method. The latter has been used to measure wave speeds.

RACE

Collecting just velocity information in one direction allows for the acquisition to be on the order of a tenth of one heartbeat. This is accomplished by projecting along the usual phase-encoding direction to examine phase changes at that position in the read direction.⁴³ The sequence diagram is shown in Figure 3-35. Usually a 2D plane is excited, but the method is best applied when a cylinder is excited and no partial voluming is present to degrade the signal.^{28, 42}

One example of RACE is shown in Figure 3-36 in the region of the aorta. The problem associated with this method comes with the nature of the projection image. When two vessels are located in the same row (column) along the projection direction, the flow velocity information is projected into the same pixel, obscuring the velocity information. However, this method can provide very high temporal resolution (equal to TR) and can be used to monitor the dynamic change of flow velocity.

Fourier Phase

Another projection method to obtain flow velocity information is called the *Fourier phase method*.^{29, 57} The sequence structure of this method is identical to a 2D sequence (Fig. 3-37). However, instead of putting the phase-encoding gradients along the phase-encoding direction, the encoding gradients are put into, for example, the slice select direction to encode flow velocity along the slice select direction. Therefore, for a Fourier phase image, one

Figure 3-35. Sequence diagram for real-time acquisition and velocity evaluation (RACE). Basically this sequence is identical to a conventional 2D sequence, except that there is no phase-encoding gradient so that all the information in the image plane will collapse into one line. The temporal resolution is equivalent to TR. The shaded portion represents the velocity-encoding gradients. Velocity-compensated gradients are used along the frequency-encoding direction. (G_s and G_r represent slice select and (radio)frequency-encoding directions, respectively.) RF, radiofrequency.

Figure 3-36. Example of a real-time acquisition and velocity evaluation (RACE) image. The velocity was measured in the region of the descending aorta. As shown, the peak velocity is about 110 cm/second, and five cardiac cycles were measured. (From Haacke EM, Smith AS, Lin W, et al: Velocity quantification in magnetic resonance imaging. *Top Magn Reson Imaging* 3:34-49, 1991.)

Figure 3-37. Sequence diagram of the Fourier phase method. Because this is a projection method, no phase-encoding gradient is used. However, a pair of encoding gradients are applied along the slice select direction to encode through-plane flow. G_z and G_x , slice select and (radio)frequency-encoding directions, respectively; RF, radiofrequency.

Figure 3-38. Example of the Fourier phase method. This image was obtained during diastole so that the common carotid arteries on both sides show high flow velocity (the signal extends far away from the DC line). Two vertebral arteries show slower velocity compared with the common carotid arteries. Moreover, the jugular vein shows slower negative flow.

axis represents spatial position and the other represents velocity. Unlike the preceding method, no conversion from phase to velocity is needed and the effects are clear from the image. Cardiac gating is used to collect velocity information during the cardiac cycle. Figure 3-38 illustrates an example application of this approach in the neck.

Again, this is a projection method, and overlapping vessels affect its accuracy. This problem may be completely eliminated when an echo planar method is used. Moreover, the inconsistent heart rate creates ghosting, which may obscure the measurement of the velocity. Aliasing has to be avoided by appropriate choice of the encoding gradient strength to meet the Nyquist criterion. The SNR may be too low for fast flow to be seen because of spin dephasing. For measuring slow flow, high signal from stationary tissue at the direct current (DC) line may obscure the flow information.

Two-Dimensional Cine

When cardiac gating is used along with short TR, a set of 2D images can be collected in a given cardiac cycle. For example, if the heart rate is T , the number of slices (phases) that can be imaged is T/TR . By interleaving a velocity-sensitive gradient structure with its negative structure and subtracting the former image from the latter image, a cine set of images with velocity in one direction is obtained.^{5, 20, 46, 47, 59}

The number of phases that can be acquired is limited by the TR and heart rate. To improve the temporal resolution, it may be better to have a delay time after the R wave to ensure that the peak velocity during systole will be sampled.

Disadvantages associated with this method include:

1. Inconsistent heart rate affects the accuracy of the velocity measurement.
2. Eddy current effects can cause distortion of phase information and hence velocities.
3. Spin dephasing can occur from higher-order motion artifacts.

4. Aliasing may occur caused by the poor choice of maximum velocity—which is the common problem usually seen with the PC method.

Bolus Tracking

One method is to use excitation of the blood followed by a parallel multislice read to find the blood that had an increasing signal.^{19, 33} Knowing the distance traveled by the blood and the time between the excitation pulse and data acquisition, it is possible to calculate the velocity of the flow. Alternatively, presaturation pulses can be applied to the normal gradient-echo sequences (2D or 3D) to saturate tissue in a fixed region but to otherwise leave the image unaffected. The dark band created by the presaturation pulse can be used as a region to view inflowing spins that enter it between the saturation pulse and data acquisition. Again, if the distance the blood travels inside the dark band and the duration between presaturation pulses and data acquisition is known, the flow velocity can be calculated (Fig. 3-39).

Several disadvantages are associated with bolus tracking methods. Motion during the sampling gradients causes distortion of the signal and, hence, of the images. Blood T2 relaxation time may affect detectability when the TE is long. Spin dephasing caused by higher-order motion artifacts may interfere with the measurement of the distance traveled by the blood. This method is also limited by the T1 relaxation of blood (which affects the appearance of the saturation band) as well as the flow profile and RF pulse profiles, which may not saturate the blood well when the profile itself is poorly defined.

Evaluating Microcirculation via Functional Images

During the past few years a great deal of interest has been generated in functional imaging in MRI.^{3, 4, 21, 22} This

Figure 3-39. Saturation pulse is applied axially with a 2D sagittal acquisition to create a dark band in the maximum intensity projection image so that the distance that blood travels from the bottom of the dark band can be used as a means to calculate flow velocity. Note the more rapid flow in the internal carotid artery (small arrow) compared with that in the external carotid artery (large arrow).

Figure 3-40. Functional imaging is possible even at 1.5 T when a long echo time (TE) sequence is used. *A*, One slice from a 3D T1-weighted scan is used to locate the central sulcus. *B*, A subtraction of poststimulation minus prestimulation by moving the right hand shows the region of the motor cortex on the left side. The motor cortex sits in the gray matter adjacent to the sulcus anteriorly.

is based on the fact that $T2^*$ is reduced when deoxyhemoglobin is present in the blood. For activation states such as motor or visual cortex stimulation, blood flow increases but the percentage of deoxyhemoglobin remains the same. Hence, $T2^*$ dephasing is not as severe and the signal increases. The subtraction of two images before and after stimulation then gives an image displaying that portion of the brain where the microcirculation increases.

An example of a 3D image used to localize the central sulcus for motor cortex studies is shown in Figure 3-40A. The subtraction of an image collected before moving the right-hand fingers from that collected when the right-hand fingers were moving in a sequential finger-touching mode is shown in Figure 3-40B. The bright region sits on the gray matter of the central sulcus. The exciting part of this research direction is that these images can be acquired with excellent resolution, and each image only takes seconds.

Processing and Image Display

To create a conventional angiography-type image from which the primary diagnosis is generally made, some special postprocessing methods and display techniques can be used. This is especially true today, thanks to the improvements in computer power; many methods are becoming

more accessible because there is little waiting for the processed images to be reviewed. Having rapid image display makes it possible to modify acquisition strategy. In most of the cases, these methods can further improve the accuracy of the images for better diagnosis. These methods can be divided into two main categories: display techniques and image-processing methods.

Display Techniques

Maximum Intensity Projection

The maximum intensity projection (MIP) approach is a method to display 3D vascular data onto a 2D projection. The idea is simple; the maximum value along any ray is used as the 2D intensity value for that pixel through which the ray intersects the plane orthogonal to the viewing direction. Consequently, it can be used to create a projection at any desired angle by rotating the viewing direction (Fig. 3-41). A cine display method can then be used to generate a movie-like display of vascular information in which the vascular structures can be viewed from all angles.

Since the concept of this method is simple and does not require intensive computation, and the results can be obtained in less than a minute, it has been widely used as a regular protocol for MRA studies. However, some

Figure 3-41. Pictorial representation demonstrating the maximum intensity projection algorithm. *A*, Oblique view. *B*, Posteroanterior view. *C*, Lateral view.

Figure 3-42. Comparison of local maximum intensity projection (MIP) and full MIP. Since the MIP algorithm tends to reduce CNR, some of the small vessels may be lost in the processing of MIP. A, A local MIP is one way to solve this problem, since only a few slices are used to perform MIP. However, the global vascular information is lost compared with full MIP (B). (From Lin W, Haacke EM, Masaryk TJ, et al: Automated local maximum-intensity projection with three-dimensional vessel tracking. *J Magn Reson Imaging* 2:519-526, 1992.)

disadvantages are associated with this method.^{2,9} If MIP is done over the entire 3D space, a great deal of noise is picked up and contrast is lost between vessels and background tissue (Fig. 3-42). Also, when fat is too bright (or signal from other tissues overwhelms the blood signal), the MIP image will lose the vessels.

Summation Methods

When all intensities are summed over a vessel, the background noise is suppressed and intersections of vessels are clearly displayed as bright. One disadvantage is that background signal can become too high and overwhelm the blood signal. One way around this problem is to sum only when the signal is above some threshold or to sum over the vessel-tracked images (see next).

Optical and Shading Methods

A computer graphic method, surface rendering, can also be applied to create the surface of blood vessels so that a shading method according to a light source can then be used to generate a visual 3D perspective image. This complements the depth information loss in the MIP images. However, to do so, the vascular information must be extracted from other nonvascular structures. Some of the vascular segmentation methods are discussed next.

Processing Methods

Single Slice and Multiplanar Reconstruction

Each slice from a set of MRA images contains blood vessel information. Whenever images are postprocessed for display, it is possible that information is lost. The best

images to look at from a 3D data set are the original unprocessed images. A simple processing method that can prove highly useful is reformatting the data along any plane through the volume; this is referred to as *multiplanar reconstruction* (MPR). Some interpolation of the image data is required, but it is usually a good technique if the 3D data are collected isotropically. The best results are obtained when the data are “sync” interpolated (i.e., the Fourier data are zero-filled to a larger matrix size and then transformed) until they are as close to isotropic as possible.⁶⁰

Vessel Tracking

The basic concepts of the vessel-tracking method are based on the assumptions that all vessels are connected with each other and that blood vessels have a reasonable uniform signal distribution.^{9, 10, 30, 36, 53, 55} Accordingly, we can extract vascular structures from other background tissue. This makes it possible to segment out the vessels so that they can be displayed independently of the background. After vessel-tracking processing, only the points that are classified as blood vessels will keep their original signal intensity and other points will be assigned a zero intensity. In this manner, the vascular information is extracted from other nonvascular structures.

This method is able to overcome the difficulties associated with MIP. Since only the points that contain vessel information are used to create the MIP images, the contrast is 100% and fatty structures or other bright tissues will not obscure vascular structures. Moreover, the processed images are ready for use in a surface-rendering program. The difficulties of this method are that it may not be able

to accurately extract vascular information when the SNR or CNR is low. Further, the nonperfect RF profiles and nonuniform receiver coils will affect the uniformity of vessel signal distribution. To overcome this problem, vessel tracking can be coupled with a traveling MIP (TMIP) method⁵⁵ to remove the signal variation at the edge of the vessel. This method is analogous to the vessel-tracking method. One of the difficulties of vessel tracking is to choose the optimum thresholds. TMIP serves as an alternate method that is less sensitive to the choice of thresholds or at least makes it possible to eliminate boxy artifacts and see where vessel tracking failed.

Superposition Methods

The ability to collect high-resolution 3D images makes it possible for accurate surgical information to be obtained from vessel-tracked images. Today, 1- to 2-mm³ 3D information obtained using MRI is standard (Fig. 3-43). Some applications even allow data for the larger vessels to be simultaneously acquired with a 3D T1-weighted study (Fig. 3-43). With the use of vessel tracking and 3D shading, both the vascular information and background tissue can then be superimposed onto each other.

Clinical Applications

The focus of this chapter so far has been on techniques, with the examples being in the head and neck. The major use for MRA has been in intracranial and carotid studies for evaluating stenosis (Fig. 3-44), aneurysms (Fig. 3-45), arteriovenous malformation (AVM) (Fig. 3-46), sickle cell disease (Fig. 3-47), and other vessel abnormalities (Fig. 3-48). The multislab 3D method can also be applied to the aortic arch with some success (Fig. 3-49).

In the chest wall, respiratory motion has long been the bane of MRI studies. Nevertheless, 3D MRA methods can be useful in both the lungs (Fig. 3-50) and heart (Fig. 3-51). In the latter case, both fat saturation and magnetization transfer contrast (MTC) are required for optimal visualization of the blood pool. In the abdomen, 2D TOF with breath-holding is most often used (Fig. 3-52). Still, 3D has found some application in the renal arteries (Fig. 3-53).

Peripheral vessels are often the most difficult to visualize because obstruction leads to slow flow and techniques based on moving blood are less likely to succeed. Two-dimensional TOF often works best in these cases, as illustrated in the upper legs of two patients (Figs. 3-54 and 3-55). The use of Gd-DTPA may prove most useful in the legs; a single high-resolution 3D coronal scan covering both legs can be accomplished in only 10 to 20 minutes. Tissue properties themselves can be used to discriminate blood from surrounding vessels in peripheral studies.

Dynamic Contrast-Enhanced MRA

As already mentioned, the use of T1-reducing contrast agents is an excellent means by which to enhance the blood signal. The previous discussion focused on a steady-state approach that required several minutes to acquire the data. For very-high-resolution studies, data acquisition might

take up to 10 minutes for a 3D volume acquisition approach with a 512×512 matrix. The main disadvantage of steady-state imaging postcontrast injection is that arteries and veins are equally bright.

Dynamic contrast-enhanced imaging refers to acquiring the data rapidly immediately following injection of the contrast agent.^{50, 52} The novel aspect of this method is that for roughly the first 30 seconds after injection, the contrast agent remains predominantly in the arteries.⁴⁰ Hence, this early time period is called the *arterial phase*, the best time for collecting data to avoid signal from the veins. If data are collected for longer than 30 seconds, the signal from the veins continues to increase. One way to avoid a problem from this increase in venous signal is to relegate it to the edges of k-space so that it only contributes to the high-spatial-frequency components. This can be accomplished by using a doubly centric (either square spiral or elliptical⁶¹) ordered k-space coverage (i.e., all data collected in the arterial phase are for the central part of k-space). After 30 seconds, the outer parts of k-space are collected from the innermost parts at early times to the outermost parts at later times.

There are two drawbacks to this approach:

1. It is possible to miss the full effect of the arterial phase; this situation sometimes leads to an infiltration of venous signal.
2. In 30 seconds, only a limited amount of k-space can be covered in 3D; this situation leads to a low-resolution scan. Current gradient strengths have helped reduce TR and TE to 5 and 2 msec, respectively, which are helpful.

For a 200-mm FOV and 200 phase-encoding steps, only 30 slices can be collected in 30 seconds. To cover a reasonably thick slab thus requires a slice thickness of 2 to 3 mm. This makes reformatting into a rotating view of the vessels inappropriate. Also, a 30-second breath-hold is already rather long.

Despite these drawbacks, this approach is becoming the method of choice for abdominal MRA, in which speed is a priority because of respiratory and cardiac motion. For imaging of the heart and the coronary arteries in particular, data are collected for only 128 msec during the cardiac cycle. For FOV = 128 mm, TR = 4 msec, 64 phase-encoding steps, and 16 slices, only 32 seconds is needed to collect images with a resolution of $1 \times 2 \times 2$ mm. This is not great resolution but does result in some very informative images of the proximal coronary vessels.

To demonstrate these principles, we show results of dynamic scans in the neck and aortic arch (Fig. 3-56), pulmonary system (Fig. 3-57), heart (Fig. 3-58), and peripheral vasculature (Fig. 3-59). For the pulmonary system, a later scan also reveals the entry of venous signal at this time. In the leg, for example, a very-high-resolution, steady-state image demonstrates the potential of increased resolution even though the data are acquired both during and after the arterial phase.

Venographic Imaging and Cerebral Blood Volume

The major focus of this chapter, and of the medical community for the past 100 years, has been on the side of
Text continued on page 81

Figure 3-43. When a large 3D volume is collected, it is possible to display the images in various orientations, for example, transverse (A) and coronal (B). B, The image was obtained by cutting through the 3D volume along the line shown. C, The maximum intensity projection of the entire volume obscures information shown in the multiplanar reconstruction image (B) or in the maximum intensity projections taken about the vessel-tracked images of the internal carotid artery (ICA) (D) or the vertebral and basilar arteries (E).

Figure 3-44. A, High-resolution carotid stenosis shown after taking the maximal intensity projection (MIP) of a 3D MRA study. B, The vessel-tracked image (similar to a local MIP) shows just the stenotic region without interference from overlapping structures. The resolution in-plane and through-plane is roughly $0.45 \times 0.9 \times 1.1 \text{ mm}^3$.

Figure 3-45. Patient study shows intracranial aneurysms. The individual images were acquired by the TE = 8 msec and TE = 5.1 msec sequences, respectively. Both sequences have a magnetization transfer contrast (MTC) pulse to suppress background tissue. Moreover, the TE = 5.1 sequence was used in the sequence structure showing in Figure 3-33. A and B, Three intracranial aneurysms are seen in both cases (small arrows). However, improved aneurysm visualization and lumen definition are obtained when the TE = 5.1 msec sequence was used (B). For example, the smaller aneurysm at the M2 section of the right major coronary artery (MCA) (A) shows flow-related dephasing and is relatively smaller as compared with that shown in B. In this example, the difference in sequence performance is especially striking since small aneurysms tend to have highly complex and fast flow. Moreover, B also shows better lumen definition and continuity at the right anterior cerebral artery (ACA) (unfilled arrow) compared with A (TE = 8 msec, open arrow). The digital subtraction angiography (DSA) image was available to compare with these two studies. It is evident from the comparison of A to C that the TE = 5.1 msec images and MIPs show the best correlation with the DSA image. (From Lin W, Tkach JA, Haacke EM, et al: Intracranial MR angiography: Application of magnetization transfer contrast and fat saturation to short gradient-echo, velocity-compensated sequences. *Radiology* 186:753-761, 1993.)

Figure 3-46. Patient study shows a large arteriovenous malformation (AVM) on the right side of brain (*small arrows*). Maximum intensity projection images are shown to compare the lumen definition in the region of rapid flow. A, The TE = 8 msec sequence shows signal dropout at the right middle cerebral artery (*large solid arrow*) and left anterior cerebral artery (*unfilled arrow*) from the flow-related dephasing. However, when the TE = 5.1 msec sequence is used (B), no signal dropout occurs in these regions and superior lumen definition is obtained (*large solid arrow, open arrow*). In both cases, the AVM is clearly seen. C, The results were compared with digital subtraction angiography (DSA). Good correlations between TE = 5.1 msec sequence and DSA were obtained. Specifically, in the regions where the TE = 8 msec sequence showed flow dephasing, there was no evidence of vessel narrowing in the TE = 5.1 msec sequence. Again, both sequences had a magnetization transfer contrast (MTC) pulse to suppress background tissue, and the TE 5.1 sequence used the sequence structure shown in Figure 3-33. (From Lin W, Tkach JA, Haacke EM, et al: Intracranial MR angiography: Application of magnetization transfer contrast and fat saturation to short gradient-echo, velocity-compensated sequences. *Radiology* 186:753-761, 1993.)

Figure 3-47. A 19-year-old female with sickle cell disease. The resulting vessel lumen definition obtained from both the TE = 8 msec and TE = 5.1 msec sequences is shown in A and B, respectively. At both the right and left MCAs (*small arrows*) and the right internal carotid artery (*large arrow*), the TE = 8 msec sequence shows signal dropout, which suggests a possible high-grade stenosis. In contrast, the TE = 5.1 msec sequence shows high signal intensity and good lumen definition in the same regions (*large and small arrows*). Again, both sequences have an MTC pulse to suppress background tissue, and the TE = 5.1 sequence used the sequence structure shown in Figure 3-33. (From Lin W, Tkach JA, Haacke EM, et al: Intracranial MR angiography: Application of magnetization transfer contrast and fat saturation to short gradient-echo, velocity-compensated sequences. *Radiology* 186:753-761, 1993.)

Figure 3-48. Base of skull MRA study. Axial collapse image from 3D phase-contrast MRA TR/TE, 22/9, flip angle 30 degrees, all-direction flow encoding, velocity encoding (VENC) = 30 cm/second. The approximate acquisition time was 15 minutes. Each slice is 1.5 mm thick. Note the loop in the posterior inferior cerebellar artery (*open arrow*) arising from the vertebral artery. (Courtesy of Fred Steinberg, M.D., Magnetic Resonance Institute of Boca Raton, Fla.)

Figure 3-49. Two-slab acquisition of the aorta arch with 3D time-of-flight acquisition method. (From Lewin JS, Laub G, Hausmann R: Three-dimensional time-of-flight MR angiography: Applications in the abdomen and thorax. Radiology 179:261-264, 1991.)

Figure 3-50. Vessels can be displayed in a maximum intensity projection format at any angle after being collected with a 3D time-of-flight sequence. (Courtesy of Piotr Wieloposki, Ph.D., Deaconess Hospital, Boston.)

Figure 3-51. Collecting 32 slices through the heart (all at end-diastole) using a 3D method avoids misregistration artifact inherent in 2D imaging and allows a high-quality multiplanar reconstruction image to be obtained (A). It is then used to search for an appropriate plane to visualize the right coronary artery (B). (From Li D, Paschal CB, Haacke EM, et al: Coronary arteries: Three-dimensional MR imaging with fat saturation and magnetization transfer contrast. Radiology 187:401-406, 1993.)

Figure 3-52. Intrarenal abdominal aortic aneurysm (AAA). **A**, Coronal black blood TurboFLASH image shows blood within the lumen (labeled) and thrombus in the wall (labeled). **B**, Coronal projection angiogram gated to systole shows both renal arteries above the aneurysm and shows poor flow enhancement downstream resulting from in-plane saturation. **C**, The same sequence in the axial plane yields good flow contrast between the lumen and thrombus in the wall, and these correlate well on the axial black blood image (**D**). (Courtesy of Paul Finn, M.D., Northwestern University, Chicago.)

arterial imaging. Although the impetus for this method is well founded on the need to understand the delivery of oxygen-bearing blood to the tissue and to visualize the arteries themselves to discover diseased vessels, the venous blood carries with it the information about tissue function. One can consider the arterial blood as reflecting *input* function and the venous blood as reflecting *output* function. If oxygen saturation in the veins could be measured, it would serve as a means to quantify the cerebral metabolic uptake of oxygen by the brain tissue.

Today, major veins in the brain can be visualized after use of a contrast agent or with a 2D TOF approach. Still, smaller veins are difficult to see with conventional methods, because the background parenchymal signal also increases thanks to its local blood volume content after the

injection of a contrast agent. By using the blood oxygenation level-dependent (BOLD) effect, however, we can design a 3D sequence to highlight the veins as dark structures while leaving the arteries with as much or more signal than the background tissue.⁵¹ We choose an echo time in which the phase of the veins becomes opposed to that of the surrounding tissue for vessels parallel to the main magnetic field. This occurs at roughly 40 to 50 msec at 1.5 T.

Now consider a two-compartment model in which λ is the venous signal fraction of blood in that voxel. If the normalized signal at any given echo time is $1 - \lambda$ for the parenchyma and λ for the veins, then when $\phi = \pi$, the summed signal of both components is $1 - 2\lambda$ and the veins will look darker than the surrounding tissue. The

Figure 3-53. Images were obtained using a 3D phase contrast technique, which included 32 slices with 2-mm-thick partitions, a 128×256 matrix, and 24-cm field of view, TR = 34 msec, and TE = 9 msec. The velocity-encoding (VENC) value was equal to 40 cm/second and two averages were used. Three-directional velocity encoding was used and resulted in an 18-minute data acquisition time. A, A normal pair of renal arteries. B, Stenosis of the right renal artery. (Courtesy of Thomas M. Grist, University of Wisconsin.)

Figure 3-54. Occluded right superficial femoral artery. Coronal cine phase contrast MRA study: TR/TE, 24/11, 30 degrees, superior inferior flow encoding, velocity-encoding (VENC) value = 60 cm/second, 40 cm-field of view. The approximate acquisition time was 2 minutes 20 seconds. This image used a projection-dephasing gradient so that the slice thickness was infinite. Note the collateral flow in the right profunda femoral artery (*small arrow*) and the deep muscular branch collateral (*larger arrow*). (Courtesy of Fred Steinberg, M.D., Magnetic Resonance Institute of Boca Raton, Fla.)

Figure 3-55. Encasement of the right iliac vein by metastatic lymph node. Coronal projection of 2D time-of-flight MRA study with arterial presaturation. This color-encoded image shows the mass (*white arrow*) encasing the iliac vein in this patient with right leg swelling. (Courtesy of Fred Steinberg, M.D., Magnetic Resonance Institute of Boca Raton, Fla.)

Figure 3-58. Contrast-enhanced image of the left coronary artery system, including the left main coronary artery, a portion of the circumflex artery, and the left anterior descending artery and its first branching into secondary vessels. Other portions of the heart and pulmonary system are also visible in the image. These data were collected in a breath-hold after the injection of a T1-reducing contrast agent. (Courtesy of Debiao Li, Ph.D., Washington University, St. Louis.)

Figure 3-57. Dynamic contrast-enhanced images of the pulmonary system immediately after injection (*top*) and 10 seconds after injection (*bottom*). Each scan is acquired in a short breath-hold. (Courtesy of Paul Finn, M.D., Northwestern University, Chicago.)

Figure 3-59. Contrast-enhanced image of the peripheral vessels. This data set has a resolution of $0.5 \text{ mm} \times 0.5 \text{ mm} \times 0.7 \text{ mm}$ and took roughly 10 minutes to collect. Because the collection was conducted with central reordering, the veins do not show up as bright (except for their edges).

larger λ is, the stronger the cancellation. A series of these images is viewed using a minimum intensity projection to show the connectivity of the venous vessels.

An example of this method along with a contrast-enhanced image for comparison is shown in Figure 3-60. Figure 3-60A represents a minimum intensity projection over five 2-mm slices from this venographic technique. Figure 3-60B represents a maximum intensity projection over the same region from a T1-weighted data set acquired after injection of contrast material.

Future Directions

MRA has come a long way since the mid-1980s. Much of its progress is due to the ingenuity of the many investigators who have contributed to this field. A great deal is also owed to the developments of better gradients and the ability to image significantly faster than before. But the real progress comes with the combination of the hardware and the methodology with the new high-relaxivity contrast agents. This advance opens the door to continued new

Figure 3-60. A, Minimum intensity projection over five 2-mm slices from the blood oxygenation level-dependent (BOLD) venographic technique. B, Maximum intensity projection over the same region from a T1-weighted data set acquired after contrast injection.

developments in the field, faster acquisition of data, better resolution, and availability of more functional information. From measuring flow to visualizing coronary arteries, MRI is making it possible to create the "vascular-visible" human (see www.mrimaging.com).

CT and MRI Anatomy of the Brain

In this section of the chapter, a brief review of the gross surface anatomy precedes the explanation of computed tomography (CT) and magnetic resonance imaging (MRI) techniques and is followed by a discussion of sectional anatomy in multiplanar axes, as seen in these two modalities.

Overview of Surface Anatomy^{10, 21, 33, 34}

Dura and Dural Structures

The brain substance is covered by cerebrospinal fluid (CSF) to allow the brain to float in the intracranial cavity of the calvarium. The brain is separated from the calvarium by pia mater, arachnoid membrane, and dura mater. The pia mater follows all the gyri and is separated from the arachnoid membrane by CSF. The outer layer of the dura is attached to the periosteum of the bony calvarium. The dura is separated from the arachnoid membrane by potential subdural space. The dural sinuses are venous structures made between the dural reflections and their opposing edges, thereby forming the superior and inferior sagittal, transverse, sigmoid, cavernous, and straight sinuses. These sinuses drain to the jugular venous system.

Ventricles

There are four ventricles within the brain that contain choroid plexus-producing CSF.

Lateral Ventricles

Traditionally, the left lateral ventricle is labeled first, followed next by the right lateral ventricle. The two lateral ventricles join to the third ventricle via the midline foramen of Monro (Fig. 4-1). The lateral ventricles are open C-shaped cavities extending from front to back within deep brain tissue. They are covered by a layer of ependymal cells, forming inner walls.

The anterior extensions into the frontal lobes are called *frontal horns*. The frontal horns are separated from each other midline by the septum pellucidum. Sometimes a cavity exists between the two layers of septum, which produces the *cavum septi pellucidi*, most commonly seen in early infancy. Posterior extension of this cavity between the two lateral ventricles produces the *cavum vergae*, which unites with the subarachnoid spaces behind the pineal region. The frontal horns are outlined laterally by the head of the caudate nuclei.

Anteriorly, the frontal horns are bound by the genu of the corpus callosum. The body of the lateral ventricles extends posteriorly over the corpus callosum and is outlined by the body of the caudate nuclei. The posterior extension of the body of the lateral ventricles forms the occipital horns.

Medially, the occipital horns are bound by the splenium of the corpus callosum, causing the peculiar shape of the occipital horns. The temporal horns are the extension of the lateral ventricles into the temporal lobes. The place where the temporal and occipital horns and the body of the lateral ventricles meet is called the *atrium* and is the most expanded part of the lateral ventricles. The main portion of the choroid plexus is located in the atrium, with some portions extending into the temporal and occipital horns.

Third Ventricle

The third ventricle is a midline structure situated between the two thalami. Anteriorly, the floor of the third ventricle is formed by the tuber cinereum; posteriorly, it is bounded by the cerebral peduncles. The roof of the third ventricle is formed by the velum interpositum. Occasionally, a cavity exists between these two layers of velum, forming the *cavum velum interpositum*, which is readily visible in coronal and sagittal MRI studies.

Fourth Ventricle

The fourth ventricle is located in the posterior fossa between the pons and cerebellum. The fourth ventricle is

Figure 4-1. Medial surface of the brain.

connected to the third ventricle via the cerebral aqueduct. CSF, which is excreted by the choroid, flows from the lateral ventricles to the third ventricle and from there to the fourth ventricle, exiting the ventricles (via the foramen of Magendie in midline and the foramen of Luschka on either side of the fourth ventricle) to drain into the cisterna magna.

Cerebral Hemispheres^{10, 15}

The two cerebral hemispheres are separated by inter-hemispheric fissures and falx cerebri. The deep fissures separate the lobes, and the sulci separate the adjacent gyri. On the lateral surface of the brain, the sylvian fissure begins anteriorly and inferiorly, separating the frontal lobe as it extends posteriorly and superiorly.

The rolandic fissure (central fissure) starts from the superior midhemisphere and extends anteriorly and inferiorly to separate the frontal lobe from the parietal lobe, ending at the junction of the anterior and middle thirds of the sylvian fissure over the lateral surface of the brain. There is no anatomic landmark to separate the occipital lobe from the parietal lobe. Three sulci over the lateral surface of the frontal lobe divide it into superior, middle, and inferior frontal gyri. Two small sulci divide the lower frontal lobe into the orbital, opercular, and triangular gyri.

Two transverse sulci divide the temporal lobe into superior, middle, and inferior temporal gyri. Heschl's gyrus is

located anterolateral over the upper superior temporal gyrus and inferior to the sylvian fissure. The postcentral sulcus separates the postcentral gyrus from the remainder of the parietal lobe. The precentral sulcus separates the precentral gyrus from the remainder of the frontal lobe. The transverse sulcus divides the parietal lobe into superior and inferior parietal gyri.

On the medial aspect, the two hemispheres are connected by the corpus callosum. The callosal fissure separates the corpus callosum from the cingulate gyrus, and it is separated from the frontal lobe by the cingulate sulcus. On the medial aspect, the frontal lobe has several sulci separating the orbitofrontal, frontal polar, anterior inferior frontal, middle internal frontal, and posterior inferior frontal gyri (Fig. 4-2). In the parietal bone, the marginal sulcus separates the paracentral lobule from the superior parietal lobe. On the medial aspect, the occipital lobe is separated from the parietal lobe by the parieto-occipital sulcus. The hippocampal gyrus is located between the medial aspect of the temporal lobe and the lateral aspect of the midbrain. The hippocampal gyrus is separated from the parahippocampal gyrus by the hippocampal sulcus. These two gyri unite to form the uncus of the temporal lobe.

Hemispheric White Matter

The axons of the neurons from the cerebral cortex and basal ganglia form the white matter. Some white matter

Figure 4-2. Medial surface of the cerebral hemisphere.

fibers connect the adjacent lobes, and some connect the two hemispheres.

The interhemispheric commissures are the following:

1. Anterior commissure, connecting the temporal lobes.
2. Posterior commissure, connecting the rostral midbrain nuclei, located behind the third ventricle.
3. Corpus callosum, a large commissure connecting the two hemispheres: it is located over the lateral ventricles and extends anteroposteriorly from the fornices, genu, body, and splenium.

The intrahemispheric commissures are the following:

1. Visual radiations, connecting the lateral geniculate bodies to the occipital lobes.
2. Superior longitudinal fasciculus, connecting the occipital lobes to the parietal and frontal lobes.
3. Arcuate fasciculus, connecting the temporal lobe to the superior longitudinal fasciculus.
4. Cingulate fibers, connecting the cingulate gyrus to the middle temporal gyrus.
5. Fornix, connecting the hippocampus to the ipsilateral mammillary body.

Posterior Fossa (Fig. 4-3)

The posterior fossa contains the cerebellum, brain stem, pons, and medulla, and it is outlined by the clivus, petrous, and occipital bones. The superior boundary of the posterior fossa is the tentorium cerebelli, which opens into the tentorial notch, permitting the connection of the infratentorial structures to the supratentorial structures. The posterior fossa is divided into two compartments by the fourth ventricle. Anteriorly, the brain stem occupies about one third of the posterior fossa; posteriorly, the cerebellum occupies the posterior two thirds.

The brain stem has three anatomically recognizable components: (1) midbrain, (2) pons, and (3) medulla.

The *midbrain* consists of cerebral peduncles anteriorly and colliculi posteriorly. The cerebral peduncles are separated from each other by the interpeduncular fossa, a CSF-filled space that merges with the suprasellar cistern. The basilar artery lies in this fossa. In the dorsal aspect of the cerebral peduncles are four nubbins of colliculi, outlined by the quadrigeminal cistern. This cistern extends laterally and anteriorly to merge with the perimesencephalic cistern. Superiorly, this space is limited by the tentorium and the great vein of Galen. Anteriorly, this space is connected to the velum interpositum over the top of the third ventricle. This space as well as the interpeduncular fossa should almost always be visible on axial CT or MRI scans. Any asymmetry of the quadrigeminal plate cistern is indicative of a mass effect.

The *pons* is characterized by anterior bulging, which is caused by the middle cerebellar peduncles and the ponto-cerebellar connections. Laterally, the pons rests against the medial posterior aspect of the petrous bone. There is a CSF-filled space between the lateral aspect of the pons and the anterior aspect of the cerebellum (floccular lobules), called the *cerebellopontine angle (CPA)*. The seventh and eighth cranial nerves cross this space to enter the internal auditory meatus. In the most caudal aspect, the ninth and tenth cranial nerves cross this space; superiorly, the fifth nerve crosses it.

The *medulla* is the most caudal portion of the brain stem and connects to the cervical cord at the level of the foramen magnum. The medulla is separated from the pons by the transverse sulcus. The pyramids and other longitudinal tracts cause minimum anterior bulging in the long axis on the ventral surface of the medulla, making its appearance different from the pons. The inferior cerebellar peduncle makes the superior protrusion on the lateral aspect of the medulla.

The two cerebellar hemispheres are joined by the midline structure of the vermis. Transverse fissures and sulci

Figure 4-3. Sagittal section of the hind brain.

(cerebellar folia) separate the laminae. The anterosuperior fissure (primary fissure) divides the cerebellum into anterior and posterior lobes. The posterior lobe is divided by another major fissure (the posterolateral fissure) in the flocculonodular and nodular lobules.

Vascular Supply^{1, 10, 14, 21}

The brain derives its vascular supply (Fig. 4-4) via two carotid and two vertebral arteries. The internal carotid artery, after giving off the ophthalmic branch and posterior communicating and anterior choroidal arteries in the supraclinoid portion, divides into the anterior and middle cerebral arteries. The anterior cerebral artery supplies blood mainly to the frontal lobe medially and mediolaterally, with some supply to the parasagittal parietal lobe. The lenticulostriate arteries, arising from the horizontal portion of the anterior cerebral artery, supply the medial basal ganglia and part of the internal capsule. The anterior choroidal branch of the internal carotid artery supplies the remaining portion of the internal capsule as well as the choroid plexus. The lenticulostriate arteries, arising from the horizontal portion of the middle cerebral artery, supply the lateral basal ganglia. At this juncture, the middle cerebral artery branches in the anterior inferior sylvian fissure into two or three branches that supply the temporal and parietal lobes. The posterior cerebral arteries, terminal branches of the basilar artery, supply the occipital lobes. The thalamoperforate arteries, arising from the posterior communicating artery and the most proximal portion of the posterior cerebral arteries, supply the thalami. The posterior temporal branch of the posterior cerebral artery supplies the posterior temporal lobe.

On axial CT scans, one can readily delineate the vascular territory by drawing a line along the anterior and posterior course of the lateral border of the lateral ventricles (see Fig. 4-4). The area between the anterior portion of the interhemispheric fissure and a line along the anterior lateral wall of the lateral ventricle is the anterior cerebral territory. The area between the posterior portion of the interhemispheric fissure and a line along the posterior lateral wall of the lateral ventricle is the posterior cerebral territory. The area between the lines along the lateral ventricle wall is the middle cerebral territory.

In high-convexity slices above the ventricular levels, almost all parasagittal areas of the frontal and parietal lobes are supplied by branches of the anterior cerebral artery, with the small portion in the posterior medial area supplied by the branches of the posterior cerebral artery. The ill-defined anterior area between the anterior cerebral artery and the middle cerebral artery is called the *anterior watershed region*. The posterior watershed area lies between the territory of the middle cerebral and posterior cerebral arteries. These two areas are more susceptible to hypotensive infarctions than other areas of the brain are.

In the posterior fossa, the inferior vermis, inferior cerebellar hemispheres, and choroid plexus of the fourth ventricle are supplied by the posterior inferior cerebellar artery and its branches, which arise from the vertebral artery before or at about the level of the foramen magnum. The area of the CPA and the anterior inferior cerebellar hemispheres are supplied by the branches of the anterior inferior cerebellar artery, which is a branch of the basilar artery. The perforator branches of the basilar artery supply the pons. The superior cerebellar arteries, arising from the

Figure 4-4. Demonstration of vascular territories on axial images. (Modified from Gonzalez C, Grossman CB, Masdeu JC: Head and Spine Imaging. New York, Churchill Livingstone, 1985, p 145.)

basilar artery, supply the superior portion of the cerebellar hemispheres.

CT Technique^{11, 22, 36}

Routine head CT is performed in an axial axis with a 15- to 20-degree angulation of the gantry to the canthomeatal line. This angulation decreases radiation to the eyes. There has been a tendency, on CT scans, to reduce this angle parallel to the canthomeatal line to match the MRI slices. The latter technique is preferred in axial imaging of the orbits and the sellar region. Slice thickness varies among different scanners and can be adjusted according to the area of interest. In routine studies, slices 8 to 10 mm thick are used. In evaluation of the orbits, the pituitary gland, the suprasellar and parasellar regions, and the CPA, thinner slices—1.5 to 3 mm thick—are needed. In these situations, coronal CT scans are also essential. Using the bony algorithm is highly important to review the bony

detail in evaluating trauma patients with facial bone and petrous bone diseases.

Contrast Studies

Except in acute trauma, excluding bleed in acute stroke, hydrocephalus, and follow-up of trauma patients, the use of intravenous (IV) contrast medium is routine. At least 100 mL, preferably 150 mL, of a 60% iodinated contrast agent should be given for optimal study results. In evaluating arteriovenous malformation, neoplastic disease (either primary or metastatic), the pituitary gland, or the sellar region, a contrast agent is essential unless renal disease or a history of sensitivity to contrast medium contradicts this usage.

In postcontrast studies, the following structures enhance physiologically without any break in the blood-brain barrier:

1. The pituitary gland and its stalk, which enhance homo-

geneously. Heterogeneity is an indication of pathologic processes.

2. Dural structures, including the interhemispheric falx, falx cerebelli, tentorium along the cavernous sinus, the tentorial notch.
3. Arterial structures in the suprasellar region, including the circle of Willis and proximal portions of the anterior, middle, and posterior cerebral arteries. The deep venous structures, such as the internal cerebral vein, vein of Galen, and dural sinuses, do show enhancement.
4. The choroid plexus within the lateral, third, and fourth ventricles. Care should be given not to confuse the nodular enhancement in the fourth ventricle, or a comma-shaped enhancement within the temporal horns connecting to the rest of the plexus in the atrium, with the enhancing mass.

Intrathecal use of contrast medium has become nearly obsolete in the evaluation of intracranial disease. This technique was commonly used for the evaluation of CPA masses, sellar region masses, and empty-sella syndrome.

MRI Technique

Routine MRI studies of the brain are performed in axial, coronal, and, sometimes, in sagittal axes in varying thickness from 5 to 10 mm. T1 images have a shorter repetition time (TR) of less than 1000 msec and a short echo time (TE) of less than 30 msec. The T2-weighted images have a long TR of more than 1500 msec. The first echo of T2 images with shorter TE is called *proton density*, or balanced T1 and T2 images. The second echo of T2 images with a longer TR of over 60 msec represents real T2 images. Studies have shown that most pathologic processes cause an increase in the water content of the brain. Therefore, T2 images are highly sensitive in detecting brain pathology.

Routinely, T1 and T2 axial and T2 coronal studies are performed. The T2 images contain a first echo with short TR and a second echo of long TR. In the evaluation of sellar and posterior fossa regions, sagittal and coronal images of 2 to 4 mm thick are needed. Specific techniques are needed to diagnose various pathologic processes; these are mentioned in related chapters.

The CSF has a long T1, which demonstrates low signal intensity in T1 images, but becomes slightly higher in intensity in the first echo T2 images. In real T2 (long TE and very long TR) images, the CSF has very high signal intensity. The basal ganglia, dentate nuclei of the cerebellum, and red nuclei of the midbrain have low signal intensities in T2 images because of their mineral content.⁶ The gray matter has a slightly higher signal intensity in relation to white matter in almost all spin-echo images. The very high signal intensity of fat in T1 images can be appreciated within the diploic space and is outlined by the low signal intensity of cortical bone. Vascular structures show signal void in all regular T1, T2, and proton-density images because of the moving protons of circulating blood. Flowing CSF can have the same effect, demonstrating signal void in the cerebral aqueduct.²⁹ The appearance of the vessels can be changed if the special technique of magnetic resonance angiography (MRA) is applied.

So far, gadolinium compounds are the only contrast

medium approved by the Food and Drug Administration that may be used intravenously. The regular dose is about 0.1 mmol/kg of body weight, and the agent must be injected at a slow rate. The same structures that enhance with IV use of contrast medium on CT scans enhance similarly on MRI scans.

Sectional Anatomy

Normal Axial CT and MRI Anatomy^{10, 11, 21, 22}

CT scans are reviewed from the caudal to cephalic levels; the scans are obtained at a 15- to 20-degree angulation to the canthomeatal line. MRI scans are generally obtained parallel to this line. These scans are divided into posterior fossa cuts of 5-mm increments and supratentorial cuts of 8-mm increments.

Posterior Fossa Cuts

Four slices from the foramen magnum to the suprasellar region are now reviewed.

Above the Foramen Magnum Level (Fig. 4-5)

The cerebellar tonsils can be seen lateral to the medulla. Most of the structures in the anterior and middle fossa are components of the base of the skull and the orbits. In the middle fossa, the foramen ovale and spinosum can be visualized if a wide window setting is used. They transmit the third branch of the fifth cranial nerve and the middle meningeal artery, respectively. The inferior portion of the cisterna magna outlines the posterior aspect of the cerebellar hemispheres.

Level of the Fourth Ventricle (Fig. 4-6)

The lower pons is seen in front of the fourth ventricle, connecting to the cerebellar hemispheres by the middle cerebellar peduncles. The pons is outlined by the anterior and lateral mesencephalic cisterns containing CSF. On MRI examinations, the seventh and eighth cranial nerves can be seen at this level. Posteriorly, the fourth ventricle is outlined by the nodulous in the midline and cerebellar hemispheres laterally. The choroid plexus within the fourth ventricle, which may enhance, can simulate a true nodule and should not be mistaken as the true parenchymal nodule.

Above the Fourth Ventricular Level (Fig. 4-7A-C)

The superior cerebellar surface is seen with separation of the two hemispheres by the superior vermis. With contrast studies, the transverse sinuses can be seen joining together in the torcula. In the middle fossa, the temporal lobes are separated from the frontal lobe by the sylvian fissure. The temporal horn, seen as a comma-shaped structure in the middle of the temporal lobe, is easily visualized in patients older than 50 years of age. Sometimes enhancement of both the choroid plexus within the temporal horn, extending to the atrium and the tentorium medially, can mimic an enhancing nodule in this region. The medial aspect of the temporal lobes bounds the suprasellar cistern and contains the internal carotid artery, the optic chiasm, the infundibulum, the mammillary bodies, and the top of the basilar artery (Fig. 4-7D-F). In the anterior fossa, the

most inferior part of the frontal lobe can be seen separated by the interhemispheric fissure.

Tentorial Level (Fig. 4-8)

The V-shaped enhancement of the tentorial notch outlines the superior vermis and junction of the pons to the midbrain. In axial scans, it is sometimes difficult to separate an infratentorial lesion from a supratentorial lesion because of partial averaging. If the lesion is lateral to

the tentorial notch, it is probably supratentorial. In such circumstances MRI plays an important role in localizing these lesions in the sagittal or coronal axis.

Supratentorial Cuts

Third Ventricular Level (Fig. 4-9)

The most inferior aspects of the frontal lobes can be seen with part of the posterior inferior interhemispheric

Figure 4-9. *Top*, Enhanced axial CT scan at the third ventricular level. *Center*, Axial T1 MRI scan at the third ventricular level. *Bottom*, Axial T2 MRI scan at the third ventricular level.

fissure medial to them. The third ventricle (a midline structure) is seen as a slitlike cavity. Generally, its transverse diameter should not exceed 5 mm. Superficially, the sylvian fissures can be seen extending medially to separate the frontal lobe from the temporal lobe. Medial to the medial aspect of the sylvian fissure, the insular cortex, external capsule, putamen, and globus pallidus are visualized. Be-

hind the third ventricle, part of the upper brain stem, including the quadrigeminal plates and cistern, can be seen.

Low Ventricular Level (Fig. 4-10)

The superior portion of the frontal horns is seen outlined by the head of the caudate nuclei. Anteriorly, the frontal

Figure 4-10. *Top*, Enhanced axial CT scan at the low ventricular level. *Center*, Axial T1 MRI scan at the low ventricular level, slightly above the CT scan level. *Bottom*, Axial T2 MRI scan at the low ventricular level, slightly above the CT scan level.

horns are shaped by indentation of the genu of the corpus callosum. The cingulate sulcus is seen separating the corpus callosum from the cingulate gyrus. With IV contrast injection, the junction of the internal cerebral vein and thalamostriate veins can be seen in the region of the foramen of Monro. Pineal gland calcification is located behind the third ventricle. Occasionally, some calcification of the habenula occurs anterior to the pineal gland calcification.

Behind the pineal gland, the great vein of Galen may show slightly increased attenuation value in precontrast studies as a result of circulating blood. With contrast injection, the vein and its junction to the straight sinus can be easily identified. The pineal gland and the vein of Galen are in the large subarachnoid space formed by the juncture of the supracerebellar cistern, the cephalic portion of the quadrigeminal cistern, and the interpositum cistern. Within the lateral ventricle, the most commonly calcified choroid plexus can be identified. On contrast studies, the anterior portion of the choroid plexus, which may not be calcified, demonstrates enhancement. The posterior horns of the lateral ventricles, including the atrium, are seen at this level.

Midventricular Level (Fig. 4-11)

The superior extension of the sylvian fissure and the superior temporal gyrus are seen. The central sulcus, slightly anterior to the sylvian fissure, separates the temporal lobe from the parietal lobe. The most superior aspect of the frontal horns is outlined anteriorly by the anterior portion of the corpus callosum, and the most superior aspect of the caudate nuclei binds them laterally. The posterior medial aspect of the occipital horns is seen bound by the white matter fibers of the splenium of the corpus callosum. The posterior portion of the cingulate sulcus, separating the cingulate gyrus from occipital lobe, can be seen connecting to the posterior interhemispheric fissure.

Above the Ventricular Level (Fig. 4-12)

The scans mainly include the frontal, the parietal, and a small portion of the occipital lobes. Because it is deep, the central sulcus can be identified in the midportion of the scan. Precentral and postcentral sulci outline motor and sensory cortices. The interhemispheric fissure can be seen in its entire length with the falx between. Generally, the falx has a higher attenuation value because of its fibrous texture and because of the presence of calcification.

Sectional Anatomy: Review of Coronal Scans

Coronal CT scanning has never equaled high-quality MRI because of significant motion artifacts and linear artifacts from dental fillings. Next, four slices are analyzed.

Frontal Horn Level (Fig. 4-13)

The frontal horns, outlined by the head of the caudate nuclei and corpus callosum, are visualized, separated by a thin layer of septum pellucidum. The sylvian fissure is seen superficially, with its superior and inferior branches separating the temporal lobe from the frontal lobe and insula.

Third Ventricular Level (Fig. 4-14)

The optic chiasm superior to the infundibulum of the pituitary gland can be identified. The suprasellar cistern outlining the optic chiasm and the superior aspect of the pituitary gland shows the CSF intensity. Some extension of this space into the interior of the pituitary fossa is now considered a normal finding rather than a manifestation of the empty-sella syndrome. In the parasellar region, the cavernous sinus is outlined by the low-intensity area of the dura, which contains the third, fourth, fifth, and sixth cranial nerves. The signal void of the internal carotid arteries within the cavernous sinus can be identified on T1 images.

Midventricular Level (Fig. 4-15)

The body of the lateral ventricles, containing portions of the choroid plexus, is seen. The precentral and postcentral sulci, the central sulcus, and the sylvian fissure are visualized, demonstrating the CSF signal in all MR images. Heschl's gyrus and the temporal lobe gyri can be easily identified. The cerebral aqueduct and midbrain structures are also visualized.

Occipital Horn Level (Fig. 4-16)

The splenium of the corpus callosum can be seen outlining the medial aspects of the occipital lobes. In the infratentorium, the cerebellar hemispheres, the fourth ventricle, the supracerebellar cistern, and the inferior, middle, and superior cerebellar peduncles are all clearly visualized on MRI studies.

Sectional Anatomy: Review of Sagittal Scans

Midsagittal Level (Fig. 4-17)

MRI has revolutionized the field by its capability to obtain sagittal and coronal images without special positioning of the patient. Therefore, patients are more comfortable, and the images are less susceptible to motion artifacts, which can arise from special positioning. Sagittal images are essential in the evaluation of sellar and parasellar lesions, posterior fossa lesions, and intraventricular lesions as well as the vascular anatomy. Sagittal images are also essential in three-dimensional (3D) visualization of intracranial lesions. At this level, the following structures can be identified:

- Venous structures—superior and inferior sagittal sinuses, the vein of Galen, and the straight sinus
- Ventricular system—third and fourth ventricles, including clear visualization of the sylvian aqueduct
- Subarachnoid spaces—suprasellar, perimesencephalic, quadrigeminal, interpeduncular supracerebellar cisterns; the cisterna magna; the central sulcus; precentral and postcentral sulci; the parieto-occipital fissure; the cingulate sulcus; and other sulci separating the frontal and parietal gyri
- Gray matter—cerebral cortices of the frontal, parietal, and occipital lobes and a comma-shaped cingulate gyrus over the corpus callosum and thalamus
- White matter—a comma-shaped corpus callosum over the lateral ventricle, the optic chiasm and optic nerves, and the pons

- Other structures—the pituitary gland, the clivus, the sphenoid sinus, the frontal sinus, the cerebellar cortex and white matter, the medulla, and the cerebellar tonsils

Parasagittal Level through the Lateral Ventricular Body (Fig. 4–18)

The following structures can be identified: the central sulcus as well as the precentral and postcentral sulci; the superior frontal gyrus; the body of the caudate nucleus; the cingulate sulcus and the gyrus; the putamen; the dentate nuclei; the cerebellar peduncles; and the parieto-occipital fissure.

Lateral Orbital Level (Cortical Level) (Fig. 4–19)

The following structures can be identified: the central, precentral, and postcentral sulci; the supramarginal gyrus; the angular gyrus; the lateral occipital gyrus; the horizontal fissure of the cerebellum; the superior and inferior semilunar lobules; the middle and inferior frontal gyri; the sylvian fissure; and the superior, inferior, and middle temporal lobe gyri.

Normal Calcifications

The following calcifications seen on CT and MRI of the brain are considered to be normal.

Choroid Plexus^{23, 33}

Calcification occurs mainly in the glomus located within the atrium of the lateral ventricles. Calcification of the choroid plexus in the third or fourth ventricle is rare. Within the lateral ventricles, calcification is rare under the age of 3 years. With age, the incidence increases, reaching 75% by the fifth decade.

Basal Ganglia⁴

Before the age of 9 years, calcification within the basal ganglia is uncommon but becomes frequent after age 40 years. This calcification is usually minimal. If the degree of the calcification is massive and associated with dentate nuclei calcification, the possibility of Fahr's disease should be ruled out.

Figure 4–18. *Top*, Sagittal T1 MRI scan through the body of the lateral ventricle. *Bottom*, Sagittal T2 MRI scan through the body of the lateral ventricle.

Figure 4-19. Top, Sagittal T1 MRI scan at the lateral orbital level. Bottom, Sagittal T2 MRI scan at the lateral orbital level

Pineal Gland and Habenula^{23, 37}

After the age of 30 years, 15% of CT scans show habenula calcification.¹⁰ However, pineal gland calcification is common, occurring in more than 83% of the patients older than age 30 years. If calcification of the pineal gland is larger than 12 mm × 12 mm × 12 mm, the possibility of a pineal gland region tumor should be considered.

Falx Calcification

Calcification of the falx is commonly seen in the posterior interhemispheric fissure in adults. If increased attenuation of the falx extends to the medial sulci, the possibility of subarachnoid bleeding should be excluded.

CT and MRI Anatomy of the Spine

Prior to a review of the normal anatomy, the techniques used in performing CT scans and MRI studies are discussed.

CT Technique^{19, 35}

CT scanning of the spine is generally done in the axial axis in 3- to 5-mm increments. In the cervical spine, thin cuts of 1.5-mm increments are necessary to evaluate disk disease. A stacking method can be used without angling the gantry (Fig. 4-20). This method has the advantage of visualizing the entire scanned area in one column without interruption to reconstruct the images in a different orientation for further evaluation. Another method involves angling the gantry and the x-ray beam perpendicular to the disk and scanning from midbody of one vertebra to midbody of the next vertebra. At each level, scans require different angulation and thus not all of the slices can be reconstructed together.

Targeting to zoom to the spine area increases the detail and resolution of the scans. Images should be filmed at two different settings, one with a narrow window for evaluation of the soft tissue shadows and disk and the other with a wide window setting for evaluation of bony structures (Figs. 4-21 and 4-22). This is very important in postintrahecal contrast studies.

Figure 4-20. Lateral view of the lumbar spine by a scanogram showing stacking method of the axial CT scanning technique. Lines demonstrate the exact level of each side. A single angled cut can be obtained through each intervertebral disk at a perpendicular angle.

Figure 4-21. Axial CT scan through the intervertebral disk in the midlumbar region. Minimal averaging of the cortex causes increased attenuation value at the periphery. At these regular window and level settings, the facet joints cannot be readily seen. The fat in the epidural space is seen within the intervertebral foramen and posterior to the thecal sac.

Figure 4-22. Axial CT scan through intervertebral disk. Wide window setting allows visualization of low attenuation of the facet joint between the facets.

Generally, IV contrast is not necessary unless the vascularity of a spinal lesion is to be evaluated. Prior to the advent of MRI, IV contrast was used for evaluation of both cervical disk herniation and postoperative spine in an attempt to visualize the epidural venous plexus.²⁷

MRI Technique^{2, 18}

MRI of the spine is routinely done in the axial and sagittal axes, rarely in the coronal axis. Our routine includes T1 and fast spin-echo images in the sagittal plane and T1 images in the axial plane in the lumbar region. In cervical spine studies, axial gradient echo is added to this menu (see Fig. 4-27). If clinically infectious diseases of the spine or intra-axial lesions are suspected, T2 axial and sagittal studies are also needed. The slice thickness is routinely 4 to 5 mm; however, it should be tailored to fit the clinical presentation. The use of IV gadolinium DTPA or DOTA is limited to evaluation of infectious disease, nonepidural neoplasms, or postoperative spine studies.^{5, 27}

Normal Anatomy*

The vertebral column comprises 32 or 33 vertebrae: 7 in the cervical, 12 in the thoracic, 5 in the lumbar, 5 in the sacral, and 3 or 4 segments in the coccygeal area.

The review of CT and MRI anatomy is divided into *osseous* and *soft tissue* structures.

Osseous Structures

Vertebral Bodies (Figs. 4-23 to 4-25)

In the cervical region (Fig. 4-24), the transverse diameter is wider than the anteroposterior diameter. The uncovertebral joint is between the uncinate process and a small depression in the inferior aspect of the vertebral body above it. The vertebral bodies become wider between the C3 and C7 levels.

In the thoracic area, the transverse and anteroposterior diameters are the same (Fig. 4-25). The vertebral bodies are cone-shaped in the axial plane. In the lumbar region, the vertebral bodies become wider in the transverse diameter. They are generally larger than at the thoracic level. In the midportion of the posterior cortex, the basivertebral vein enters into the vertebral body, bifurcating into branches and making a Y-shaped defect in the axial images.

On CT studies, dense cortical bone has very high attenuation value with less attenuation in the center because of cancellous bone. On axial scans, if a slice averages through the end plate and disk space, the central part of the vertebral body will have decreased density, mimicking a destructive process (Fig. 4-23C).

Vertebral bodies are isointense on T1 images (Figs. 4-25, 4-26B, and 4-27B), with a decrease in signal intensity on gradient echo images. The cortex with dense bone has a low signal intensity on T1 images. On T2 images, the signal intensity of vertebral bodies decreases.

*See References 2, 5, 7-9, 12, 13, 16-18, 25, 28, 31, and 32.

Pedicles

Pedicles extend from the vertebral bodies posteriorly to reach the articular pillars. They are very short in the cervical area and increase in length cephalocaudally. In the thoracic area, the pedicles are located in the upper half of the vertebral bodies, resulting in a higher location of the intervertebral foramina in relation to disk spaces. In the lumbar region, the pedicles are larger in the superior aspect than in the inferior aspect. On axial scans, the pedicles are seen outlining the lateral borders of the spinal canal, forming a full circle of bone. In the scans above or below the pedicles, the lateral borders of the canal are interrupted by the intervertebral foramina.

Laminae (Fig. 4-26; see Fig. 4-23)

The two laminae at each level extend posteriorly and medially to meet in midline and fuse into the spinous process. The superior fusion is slightly more anterior than the inferior fusion. In the thoracic area, the laminae are broader and shorter, with some overlap. In the lumbar region, the laminae do not overlap. A larger space is found between adjacent laminae in the upper lumbar spine than in the lower lumbar spine.

Spinous Processes (see Figs. 4-23 and 4-26)

The spinous processes start from the junction of two laminae and extend posteriorly and downward. In midcervical areas, they have a bifid appearance. In the thoracic region, they are slender and longer. In the lumbar area, they are larger and taller with rectangular shape on a lateral view.

Transverse Processes (Fig. 4-27; see Fig. 4-23)

In the cervical area, the transverse processes have an anterior and posterior component that meet laterally in a horizontal plane to form the transverse foramina. These foramina permit the passage of the vertebral arteries from the C7 to the C2 level (Fig. 4-27).

In the thoracic region, the transverse processes are close to the heads, necks, and tubercles of the corresponding ribs. In the lumbar area, the transverse processes extend laterally and posteriorly. The transverse processes of L1 and L5 are thicker and shorter.

Articulating Pillars

The articulating pillar is created by the superior and inferior facets.

Intervertebral Foramina (see Figs. 4-23 and 4-27)

The foramina are bounded medially by the posterior vertebral body and the intervertebral disk space, superiorly by the inferior margin of the upper vertebral pedicle, and inferiorly by the superior pillars. The intervertebral foramina contain corresponding spinal nerve, veins, fat, arteries, and connective tissue. At the thoracic level, the foramina are at the lower half of the vertebral bodies. The neck of the rib participates in creating the boundaries of the foramen anterolaterally.

In the lumbar region, the foramina are larger and longer.

Text continued on page 116

Figure 4-23. *Top*, Axial CT scan through the upper half of the vertebral body demonstrating the full circle of bony canal made by the vertebral body, pedicles, laminae, and the spinous process. *Center*, Axial CT scan through the intervertebral foramen in the midlumbar region. Low attenuation of fat and the slightly increased attenuation of ligamentum flavum help to determine the border of the thecal sac. *Bottom*, Axial CT scan through the midvertebral body in the lumbar region. The ganglion is seen in the most proximal portion of the intervertebral foramen (canal) surrounded by fat.

Figure 4-24. *Top*, Axial CT scan through a cervical vertebral body, showing the transverse foramina for passage of the vertebral arteries. *Bottom*, Axial CT scan through the intervertebral foramen in the midcervical region. The large amount of cerebrospinal fluid in front and back of the cervical cord helps to delineate the cervical cord and the roots.

Figure 4-25. Axial T2 MRI at the midthoracic level. The thoracic cord has a more rounded appearance. Note the larger subarachnoid space posteriorly with high signal intensity in this T2 study.

Figure 4-26. *Top*, Axial T1 MRI through the facet joints. The ligamentum flavum, medial to the lamina, is seen bordering the posterior lateral aspect of the canal. The thecal sac is separated from the ligament by fat. *Center*, Axial T1 MRI scan through midportion of the vertebral body in the lumbar region. Fat with high signal intensity is seen anterior to the thecal sac and within the intervertebral foramen. The nerve root ganglion is seen inside the foramen. Dense cortical bone has lower signal intensity relative to the rest of the vertebral body. *Bottom*, Axial T1 MRI of fat in the epidural space helps to outline the thecal sac. Ligamentum flavum, which has a low-signal-intensity border, outlines the canal posterolaterally.

Figure 4-27. *Top*, Axial gradient-echo MRI scan through the intervertebral foramen in the midcervical region. The high-signal-intensity cerebrospinal fluid outlines the cervical cord and the roots (similar to the appearance on intrathecal contrast-enhanced CT scan). Any protrusion into the foramen by degenerative joint disease or disk herniation can be appreciated in this imaging. *Bottom*, Axial gradient-echo MRI scan in the midcervical region, just caudal to the top image, showing the distal end of the intervertebral foramen (canal). The transverse foramina are seen allowing passage of vertebral arteries.

They have a canal-like appearance and are oriented anteriorly and laterally.

On MRI studies, the high signal intensity of the fat on the T1 within the epidural space and the foramina outlines the isointense nerve root, covered by the low signal intensity of CSF (see Fig. 4-26B, C). On gradient-echo images, the CSF becomes high in signal intensity, outlining the diminished signal intensity of the spinal nerve root and cord (Fig. 4-28B).

On CT scans, the water attenuation value of the nerve root and ganglion are seen within the intervertebral foramina, with some low attenuation of the fat in the epidural space (see Fig. 4-23B, C). The entire length of the foramen, which is actually a canal, can be seen by following the scans from cephalic to caudal levels.

Spinal Canal^{8, 35}

The canal measures about 27 mm at the C1 level and 21 mm in the lower cervical area in the sagittal midline

plane. The lowest normal diameters of the canal are 12 mm in the lower cervical area and 15 to 16 mm at C1-C2.³²

In the thoracic area, the spinal canal is completely outlined by bones in the upper half, with some discontinuity of the bone in the lower half to form the facet joints. The canal is rounded and is fairly constant in size and contour, with a triangular appearance in the lower region. In the lumbar area, the canal has a round to oval shape in the upper lumbar region and a triangular shape caudally. In the lower lumbar region, the laminae bow inward with some indentation toward the canal.

On T1 sagittal images, the canal can easily be measured in the anteroposterior diameter (Figs. 4-28 to 4-30). Anteriorly, the canal is outlined by a low signal from the posterior cortex and the posterior longitudinal ligament. The spinal cord, which is isointense on T1 images, is outlined by the low signal intensity of CSF (Figs. 4-28 and 4-29). On gradient images, the intensity of the cord and that of CSF are similar, making it very difficult to measure the spinal cord.

Figure 4-28. *Top*, Sagittal T1 MRI in cervical area. The intervertebral disk has slightly higher intensity relative to outlining cortical bone and the ligaments. The subarachnoid space is larger from C1 to C3 posteriorly, whereas it becomes larger in the midcervical and lower cervical areas anteriorly. *Bottom*, Sagittal gradient-echo study of cervical spine showing increased signal intensity of cerebrospinal fluid similar to that in a T2 study. The healthy intervertebral disk has higher signal intensity as a result of its water content. The anterior and posterior longitudinal ligaments can readily be seen outlining the spinal canal.

Figure 4-29. *Top*, Sagittal T1 MRI study of the thoracic spine. There is more cerebrospinal fluid posteriorly in the thoracic area. The spinal cord can be measured more accurately with this technique than with gradient-echo or T2 studies. *Bottom*, Sagittal T2 MRI of the thoracic spine. In this image, the border to the thoracic cord is not as clear as in the top image. The high signal intensity indicates a healthy disk.

Figure 4–30. *Top*, Sagittal T1 MRI study of the lumbar spine in midline. The epidural fat behind the thecal sac and in front of the distal lumbar area shows high signal intensity. The intervertebral disk space has slightly lower intensity relative to the vertebral body. *Bottom*, Sagittal gradient-echo MRI study of the lumbar area in midline. The cerebrospinal fluid has slightly increased signal intensity. The anterior and posterior longitudinal ligaments are seen outlining the vertebral bodies and intervertebral disk spaces. The interspinous ligaments connect the two adjacent spinous processes.

On T2 images, the CSF has high signal intensity, thereby outlining the decreased intensity of the cord. Care should be taken that the cord measurements on T2 images may be less than their actual size because of partial-averaging volume of the CSF and the cord. On CT scans, the canal border can be identified by the bony margins of the spinous processes, laminae, and posterior aspects of the venous processes (see Figs. 4-22 and 4-23). The cord in the cervical region can be seen without intrathecal contrast (see Fig. 4-24). In the lumbar and thoracic areas, however, intrathecal contrast is needed to evaluate the spinal cord and intracanal abnormalities. The fat within the epidural space and the intervertebral foramina help to outline the disease processes affecting the margins of the spinal canal.

Soft Tissues, Joints, and Ligaments

Intervertebral Disk

The disk spaces separate the two adjacent vertebral bodies. No disk space exists between C1 and C2. The disk comprises the central portion of the nucleus pulposus and the peripheral segment of the annulus fibrosus. The nucleus pulposus is softer with greater water content. The annulus fibrosus comprises hard fibrous tissue surrounding the nucleus. Because of the curvature of the disk spaces in the cervical area, angulation of the gantry to cut through the disk is not always possible unless slices 1.5 mm thick are taken. In the cervical region, the disks are thinner compared to those of the thoracic and lumbar regions. The disks have an attenuation value of 50 to 110 Hounsfield units. The thoracic disks are thinner but larger in the cross-sectional area. In the thoracic area, ligaments connect the crest of the head of the ribs to corresponding disk spaces.

The lumbar disks are thicker and larger. The height of a lumbar disk varies from 8 to 12 mm. The posterior margins are concave or flat except at the level of L5-S1, and these can be convex, bulging into the canal centrally. On T1 images, a disk will have low intensity (Figs. 4-26A and 4-27A), with increased intensity on gradient-echo images (Fig. 4-30); see Figs. 4-28 and 4-29) and T2 images.

Especially on T2 images, the disk should have high signal intensity (see Fig. 4-29B). Decreased signal intensity on T2 images is indicative of a decrease in water content, a manifestation of disk degeneration. On sagittal images, anterior and posterior disk margins appear outlined by the anterior and posterior longitudinal ligaments (see Fig. 4-30). Discontinuity of the ligament may suggest a tear resulting from a herniated disk.

On CT scans, the water attenuation of a disk is similar to that of muscle (see Fig. 4-22). The disk border should not extend beyond the posterior aspect of the adjacent vertebral bodies, except at the L5-S1 level, where the disk bulges in midline (Fig. 4-31). With degeneration, a disk will bulge diffusely, extending beyond the border of the vertebral body. Evidence of gas (air density) within a disk suggests the vacuum phenomenon or is a manifestation of an infectious process that requires further investigation. On CT scans, disks and ligaments cannot be distinguished because of their similar attenuation values.

Uncovertebral Joints³

In the cervical area, these joints are between the uncinate process and the adjacent vertebral body. With degenerative joint diseases and narrowing of the disk spaces, the joint space also becomes narrowed.

Facet Joints (Fig. 4-32; see also Fig. 4-26)

These are joints between the superior articulating facet of the lower vertebra and the inferior facet of the upper vertebra. They are oriented halfway in the sagittal and axial axes. The superior articulation facet of the lower vertebra is always anterior to the inferior articulating facet of the upper vertebra. The facet joints are oriented almost in the coronal plane in the thoracic region. The articular surfaces are flat, with some convex shape to the nonarticulating parts. Joint spaces are found between the heads of the ribs and the vertebral bodies as well as between the ribs and the transverse processes.

Figure 4-31. Axial CT scan through the intervertebral disk space of L5-S1, demonstrating the flat, slightly concave border of the disk posteriorly, a normal finding. The posterior aspect of the disk spaces is concave in remainder of spinal column.

Figure 4-32. *Top*, Sagittal T1 MRI scan in the lumbar spine. The boundary of the intervertebral foramen (pedicle, posterior inferior portion of the vertebral body, intervertebral disk, anterior superior aspect of superior articulating facet) can readily be identified in this para-midline sagittal plane. *Bottom*, Sagittal MRI study of lumbar area in para-midline plane. The very low signal intensity of the cortical bone helps to visualize the upper and lower border of the intervertebral disk. The foramina and the facet joints are clearly visualized on this image. Defects within the pars interarticularis and foraminal narrowing can be appreciated in this axis.

The facet joints are oriented in a parasagittal plane in the upper lumbar area with an oblique orientation in the lower lumbar area. The joint spaces are 2 to 4 mm³. The synovium extends into the canal to attach to the ligamentum flavum that covers the anterior end of the joint space. Sagittal MRI studies are useful for evaluation of the facet joints and their orientation (see Fig. 4-32).

Spondylolysis defects can easily be identified on these images. In addition, the fluid within the joint space, which has signal intensity similar to that of water, can be seen outlined by the very low signal of the dense cortical bone of the facets and the isointense ligamentum flavum. Narrowing of the facet joints and spurring can easily be detected on axial CT scans or MRI studies. With CT scans, the dense cortex of the articulating facet is separated by the low attenuation value of the facet joint space (Fig. 4-22).

Ligaments

Anterior Longitudinal Ligament (see Figs. 4-28 to 4-30). This ligament starts from the axis as the anterior atlantoaxial ligament and extends to the sacral segments, connecting the anterior aspects of the vertebral bodies and disk spaces (see Fig. 4-30). On CT scans, the ligament cannot be separated from the bony structures and the disk space. Thickening of the ligament results in a narrowing of the canal in the sagittal diameter.

Posterior Longitudinal Ligament. This ligament begins on the posterior surface of the axis and extends to the sacrum to connect the posterior aspects of the vertebral bodies and disk spaces (see Fig. 4-30).

Interspinous Ligament (see Fig. 4-30). This ligament connects the spinous processes. It has a slightly higher attenuation value, making it recognizable on CT scans.

Nuchal Ligament. This ligament connects the base of the occipital bone to the spinous processes of C1 to C7 (see Fig. 4-28B).

Ligamentum Flavum. This ligament has both stretchability and retractability functions, and it is attached to the laminae. It does have a higher attenuation value that can

be identified on CT scans. It measures 3 to 5 mm in thickness and extends to the level of the first sacral segment (see Fig. 4-21). The ligamentum flavum and interspinous ligaments can easily be seen on T1 MRI images (Fig. 4-26A). Their hypertrophy results in narrowing of the canal, posteriorly and laterally.

Epidural Space (see Figs. 4-23, 4-26, and 4-30). This space contains fat, vessels, and neural elements. In the cervical area, the anterior space is thinner and less visible on CT scans. The internal vertebral veins have no valves, thereby facilitating the spread of infectious processes and metastasis. The anterior and posterior epidural spaces can be visualized by IV injection of contrast medium for evaluation of extradural diseases. The basivertebral vein penetrates the vertebral body to join the internal plexus. The external vertebral plexus lying outside of the vertebral bodies is linked to the internal plexus by veins passing through the ligamentum flavum and the neural foramina.²⁰

The epidural space has more fat posteriorly in the thoracic region,¹³ with a minimal amount anteriorly (see Fig. 4-29A). The venous structures of the epidural space are similar in the cervical and thoracic areas except for a possible link between the anterior and posterior vertebral plexus with the intercostal veins and the azygous system.³⁰ The epidural space is larger in the lower lumbar area. This is helpful in outlining the disk border. Obliteration of fat in the epidural space is an indication of an epidural process.

Dura Mater, Intradural Space, and Spinal Cord. The dura mater is a hard membrane that forms a sleeve around the subarachnoid space to cover the cord and intracanal component of the nerve roots. It extends beyond the canal to cover the root within the foramina and fuses with the perineurium of the spinal nerves to close the extension of the subarachnoid space (see Fig. 4-27). The cervical cord is wider in the ventral surface and is indented by the anterior median fissure (see Fig. 4-27). The posterior median fissure is shallow.³¹ The cervical cord is larger from C3 to C6 as identified on myelography. Because of the larger subarachnoid space in the cervical area, the cord can easily be seen on plain CT scans without intrathecal contrast (see Fig. 4-24). With intrathecal contrast, visualization

Figure 4-33. Reconstructed image of a cervical spine CT scan with enhancement by intrathecal contrast CT at the craniocervical junction. The upper cervical cord, medulla, pons, cerebellar tonsils, and vermis are surrounded by contrast material.

of the cervical cord and roots can be enhanced significantly (Fig. 4-33).

Eight pairs of cervical spine nerves exist. The first cervical spine nerve passes posterior to the atlanto-occipital joint. The remaining nerves pass through the intervertebral foramina. The number of nerve roots in the cervical region corresponds to the lower vertebral count number (e.g., the root passing through the C5-6 foramen is the C6 that lies medial to the pedicle of C5). In the thoracic area, the cord has a more rounded appearance^{26, 30} (see Fig. 4-25). The cord becomes larger from T9 to T12,³² terminating in conus with rapid tapering in its diameter.

In the upper thoracic region, the location of pathology is about two vertebrae higher than the corresponding clinical level. The discrepancy increases to three segments in the lower thorax. The spinal nerves are difficult to visualize on plain CT scans. The dura terminates at the level of S2 and fuses with the filum terminale to terminate at the coccyx. The lumbar canal contains the conus, cauda equina, and the filum terminale. The conus medullaris ends at the L1-2 disk space (see Fig. 4-30), becoming the filum terminale. In the lumbar area, the spinal nerves can be seen on plain CT scans, exiting medial to the corresponding pedicles (see Figs. 4-23A and 4-31).

Intracranial Neoplasms

Stephen A. Kieffer, Ja-Kwei Chang

Primary neoplasms of the central nervous system (CNS) represent nearly 10% of all tumors reported in large autopsy series.²⁸⁶ The American Cancer Society estimates that nearly 17,000 primary intracranial neoplasms were newly diagnosed in the United States in 1999.¹⁸² The brain and meninges are also common sites of secondary tumor implantation; hematogenous metastases likely account for more intracranial tumors than primary brain neoplasms.^{203, 264}

Approximately 10% of primary brain tumors occur in children. Brain tumors, the most common solid neoplasms of childhood, are second in frequency only to the leukemias among childhood malignancies.^{25, 352} Although the incidence of intracranial neoplasms and the proportion of higher grade (more malignant) tumors are both considerably lower in children than in adults, primary brain tumors are nevertheless the leading cause of cancer related deaths in children younger than 15 years.²⁴⁵

In 1993, the World Health Organization (WHO) issued a major revision of its classification system for tumors of the brain and CNS.^{163, 303} This system is based on the presumed cell of origin and assigns a numerical grade estimating the biologic potential of the particular neoplasm.³⁰³ The revised classification has been widely accepted around the world. A further revision issued in 2000 serves as the basis for the organization of this chapter (Table 5-1).¹⁶⁴

Approximately 40% of intracranial neoplasms are of neuroepithelial origin, including astrocytomas, glioblastomas, oligodendrogliomas, ependymomas, medulloblastomas, and less common variants and combinations of these cell types.³⁴² Meningiomas (15% to 18%), pituitary adenomas (7% to 8%), and schwannomas (6%) also occur relatively frequently within the cranial vault.³⁴²

The presenting symptoms in most patients with intracranial neoplasms are often nonspecific, initially mild, or both. Headache, reported by about 50% of patients with brain tumors, is the most common initial complaint.^{85, 264} The headache is frequently described as diffuse and more severe in the morning and often dissipates in a few hours even without treatment.⁸⁵ When unilateral, it can accurately indicate the hemisphere involved by tumor.¹⁰⁸ Episodes of confusion or change in behavior also commonly bring the patient to the physician. Unfortunately, headache and personality change are often attributed to other causes.²⁶³ Manifestations of focal cerebral dysfunction (e.g., unilateral weakness, aphasia) are less common presenting complaints, but a careful history often reveals the prior occurrence of less specific symptoms.

It is the progressive nature of the symptoms that eventu-

ally leads to consideration of brain tumor as a diagnostic possibility, but this is often late in the course of the tumor. An exception to this more typical pattern—insidious onset and slow progression with resultant late diagnosis of intracranial neoplasm—is the abrupt onset of seizures, which are typically focal but may become generalized and lead to loss of consciousness.⁸⁵ Seizure is the presenting complaint in 15% to 95% of patients with brain tumors, occurring more frequently in low grade gliomas and meningiomas than in higher grade gliomas and lymphomas.⁸⁵

Intracranial neoplasms produce symptoms by three mechanisms³³¹: (1) infiltration and destruction of normal tissues (e.g., by a glioblastoma), (2) localized cortical irritation or depression (e.g., by a convexity meningioma), or (3) expansion within the rigid and unyielding cranial vault. Edema of the white matter adjacent to the tumor is often extensive and may account for much of the patient's symptomatology and neurologic deficit,^{106, 286} an impression that is verified by the striking improvement, both clinical and on imaging, exhibited by many patients after systemic administration of corticosteroids.⁷⁵

An increase in intracranial pressure above the normal level of 180 mm H₂O commonly accompanies an expanding intracranial mass. Headache, nausea, vomiting, and sixth cranial nerve palsy may reflect increased intracranial pressure.⁸⁵ Prolonged or significantly elevated intracranial pressure manifests clinically as loss of attentiveness, apathy, and drowsiness.³²⁸ These signs of depressed cerebral function are most likely caused by diminished cerebral blood flow secondary to distention of the intracranial contents. This distention also produces traction on the overlying meninges, probably accounting for the headache, nausea, and vomiting that occur with chronic intracranial hypertension.

Diagnostic Imaging

The goals of diagnostic imaging in the patient with suspected intracranial tumor include *detection* of the presence of a neoplasm, *localization* of the extent of the tumor (including definition of involvement of key structures and assessment of the presence and severity of secondary changes, e.g., edema, herniation, hemorrhage), and *characterization* of the nature of the process.

Imaging (usually magnetic resonance imaging [MRI]) is also extensively utilized in treatment planning before surgery or radiation to define the gross tumor margins and to permit selection of the safest approach to the lesion.²⁷⁶

Table 5-1. Classification of Tumors of the Nervous System**Gliomas***Astrocytomas*

- Circumscribed astrocytomas
 - Juvenile pilocytic astrocytoma
 - Pleomorphic xanthoastrocytoma
 - Subependymal giant cell astrocytoma
- Diffuse astrocytomas
 - Low grade astrocytoma
 - Optic pathway glioma
 - Brainstem glioma
- Anaplastic astrocytoma
- Glioblastoma multiforme
- Gliomatosis cerebri
- Gliosarcoma

Oligodendrogliomas

- Low grade oligodendroglioma
- Anaplastic oligodendroglioma

Ependymomas

- Ependymoma
- Subependymoma

Choroid plexus tumors

- Choroid plexus papilloma
- Choroid plexus carcinoma

Nonglial Tumors*Neuronal and mixed neuronal/glia tumors*

- Ganglioglioma
- Gangliocytoma
- Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos)
- Desmoplastic infantile ganglioglioma
- Dysembryoplastic neuroepithelial tumor
- Central neurocytoma

Pineal parenchymal tumors

- Pineoblastoma
- Pineocytoma

Embryonal tumors

- Medulloblastoma
- Supratentorial primitive neuroectodermal tumor

Tumors of the Cranial Nerves

- Schwannoma
- Neurofibroma
- Malignant peripheral nerve sheath tumors

Tumors of the Meninges

- Meningioma
- Hemangiopericytoma
- Mesenchymal nonmeningothelial tumors
- Melanocytic tumor
- Hemangioblastoma

Tumors of the Hematopoietic System

- Primary CNS lymphoma
- Secondary CNS lymphoma
- Histiocytic lesions
- Granulocytic sarcoma (chloroma)

Germ Cell Tumors

- Germinoma
- Teratoma
- Other germ cell tumors

Tumors of the Sellar Region

- Pituitary adenoma
 - Microadenoma
 - Macroadenoma
- Craniopharyngioma
- Rathke cleft cyst
- Tumors of the neurohypophysis
- Chordoma

Metastatic Tumors

- Metastases to the brain
- Metastases to the skull and intracranial dura
- Leptomeningeal metastasis (leptomeningeal carcinomatosis)

Based on the World Health Organization (WHO) Classification (2000 Revision). This classification has been adapted and modified from Kleihues P, Cavenee WK (eds): Pathology and Genetics of Tumours of the Nervous System. Lyon, International Agency for Research on Cancer, 2000.

Functional MRI is increasingly employed preoperatively to determine the location of functionally eloquent cortex, which can then be avoided during an operative approach.¹⁸⁵ Interactive computerized neuronavigational devices utilize these data (1) to allow administration of very high doses of precisely focused radiation to small (up to 3 cm) intracranial tumors while sparing the adjacent normal brain^{260, 325} and (2) to accurately register the previously acquired image data set onto intraoperative space, thus enabling precise intraoperative localization of surgical instrumentation relative to tumor margins, key vascular structures, and other critical anatomy.^{202, 325} A relatively new and highly promising application is image guided surgery, in which the entire surgical resection is guided by direct real time MRI in the operating room environment.³³⁷

Followup assessment of intracranial neoplasms utilizes CT and MRI and related techniques extensively, including MR spectroscopy and MR perfusion weighted imaging, to monitor post-treatment complications and to detect the presence of residual or recurrent tumor.^{231, 276}

Computed Tomography

Before the introduction of computed tomography (CT) in the early 1970s, confirmation of the presence or absence

of brain tumor involved the use of invasive diagnostic procedures (e.g., cerebral angiography or pneumoencephalography) that required hospitalization and carried some morbidity and risk. Clinicians were often reluctant to submit patients with uncertain history and findings to such risks.

The advent of CT significantly altered the method and timing of diagnostic evaluation of the patient with suspected brain tumor.^{13, 14} CT evaluation of the brain is relatively noninvasive and is therefore easily and rapidly accomplished. In the mid-1970s, CT emerged as the primary diagnostic screening modality for the *detection* of intracranial disease. Areas of structural abnormality (e.g., tumors) appeared on CT as regions of altered tissue radiographic density.¹⁵ Accuracy of *localization* with CT exceeded the accuracy that could be achieved by cerebral angiography or other invasive diagnostic procedures. Another important advantage of CT was the demonstration of *no* disease in the symptomatic patient who did not have a neoplasm or other structural abnormality, thus affording reassurance to the patient and physician and avoiding costly hospitalization and more invasive or more hazardous diagnostic procedures.^{13, 355} Conversely, CT occasionally revealed abnormalities (including tumors) that were not suspected clinically in patients with relatively nonspecific complaints.^{14, 346}

Magnetic Resonance Imaging (MRI)

Since its introduction as a clinically practicable diagnostic modality in the early 1980s, MRI has rapidly earned recognition as the optimal screening technique for the detection of most intracranial neoplasms.^{10, 11, 37, 172, 275} Compared with CT, MRI using spin echo, gradient echo, and combination spin and gradient echo pulsing sequences before and after intravenous (IV) administration of paramagnetic contrast agents provides inherently greater contrast resolution between structural abnormalities and adjacent brain parenchyma and has proved to be even more sensitive in the detection of focal lesions of the brain.^{158, 172, 275} Early experience suggested that 3% to 30% more focal intracranial lesions could be identified on MRI than on CT.^{37, 100}

Lesions and tissues with increased water content appear even more conspicuous on T2-weighted MR images than on CT images obtained after IV infusion of contrast agents.³⁶ Delineation by MRI of normal and abnormal soft tissue anatomy in the posterior cranial fossa, near the base of the skull, and in other areas of the brain that lie adjacent to dense bone is considerably better than with CT because of MRI's lack of the beam hardening artifacts secondary to absorption of x-rays in bone seen on CT.³⁹ Accuracy of lesion localization on MRI is enhanced by its direct multiplanar capability, which permits acquisition of images in the coronal and sagittal planes in addition to the axial plane conventionally used in CT. MRI offers superior contrast resolution, including greater sensitivity for the detection of subacute and chronic hemorrhage in association with tumors and other structural lesions of the brain.^{9, 276} The ability with MRI (using conventional anatomic imaging protocols as well as MR angiography sequences that display blood flow) to visualize vessels supplying and draining structural lesions in the brain adds yet another important dimension of information that can contribute to the diagnostic assessment.

Even with current state of the art equipment utilizing very high magnetic fields and rapidly switching gradient coils, MR nevertheless suffers two disadvantages in comparison with CT in the assessment of intracranial structural abnormalities: (1) MRI requires significantly longer image acquisition times, and (2) abnormalities involving cortical bone, intratumoral calcification, and hyperacute hemorrhage are more clearly and accurately assessed with CT. Newer multi-slice helical or spiral CT scanners are capable of providing highly collimated submillimeter thickness sectional images in extremely short acquisition times, and thus areas of hyperostosis or bone destruction, intratumoral calcifications, and early intratumoral or peritumoral hemorrhage are more completely defined with greater certainty on CT than on MRI.^{36, 275} The much faster acquisition capability of current CT units strongly favors their use in patients who are critically ill or medically unstable. Also, in patients with magnetically controlled cardiac pacemakers and other internal paramagnetic metallic devices, the risk of the MRI magnet interacting with such devices may preclude the use of MRI.²⁹⁷

Given both the higher cost and more restricted availability of MR equipment to date as well as continuing improvements in CT equipment and scanning techniques that per-

mit shorter examination times with improved spatial and contrast resolution, it is not surprising that CT remains a major imaging technique for the followup of intracranial mass lesions. In current clinical practice, initial diagnosis and localization of brain lesions are most often accomplished with MRI, but the imaging modality of convenience for followup studies is often CT.

Diagnostic Uncertainties

Resolution of soft tissue anatomy underlying thick dense bony structures remains a significant problem with CT. Small hyperdense lesions at the periphery of the brain may be overlooked on CT because they may "blend" with the adjacent bone unless relatively high center and window width settings are employed.²⁸⁷

Small lesions with a diameter less than or approximating the thickness of the CT or MR "slice" may not be accurately depicted, because the density or signal intensity reflects averaging of the lesion and the adjacent tissues included in the slice volume.⁹¹ Unless very thin slices are employed, small tumors may thus be obscured.

Localization of a peripherally situated neoplasm as either within (intraaxial) or outside (extraaxial) the brain may be difficult on CT. The presence of inward "buckling" of the adjacent gray-white matter junction indicates that the tumor is extracerebral (see Fig. 5-36A); when this sign is demonstrated, it appears to be reliable and valid, but it was identified on CT in only 40% of one large group of superficially situated meningiomas.¹¹³ In contradistinction, peripherally located intraaxial tumors tend to spread and widen the adjacent white matter, displacing the gray-white junction outwardly.^{16, 276} Other factors that may aid in establishing on CT that a lesion is extraaxial are the demonstration of adjacent bone destruction or hyperostosis (see Fig. 5-36), widening of the surface subarachnoid spaces adjacent to the margins of the lesion, and continuity of the tumor with the falx or tentorium.^{218, 276}

CT in the modified coronal projection and MRI in the true coronal projection have proved to be of considerable help in the evaluation of questionable areas at the periphery of the brain, where the previously described problems of volume averaging and lesion detection or localization occur.²¹⁰ Coronal MR images are also valuable in establishing whether a tumor is supratentorial or infratentorial, because the tentorium is oriented nearly horizontally, and imaging in the coronal plane allows precise determination of the relationship of adjacent mass lesions to this structure.²⁷⁶ Multiplanar MRI also increases the diagnostic precision with which paraventricular masses can be differentiated from intraventricular masses. Paraventricular tumors characteristically displace the choroid plexus and compress the lateral ventricles, whereas intraventricular masses cause local ventricular expansion and generally conform to the shape of the ventricle.¹⁷³

Contrast Enhancement

IV administration of iodinated contrast medium causes a transient increase in the attenuation coefficient of normal

gray matter and accentuates the difference in radiographic density on CT images between white matter and gray matter in the normal brain.¹¹² Similarly, IV administration of paramagnetic contrast agent (e.g., gadolinium chelates) transiently induces shortening of both the T1 and T2 relaxation times of normal gray matter and accentuates the difference in MR signal intensity between normal cerebral gray matter and white matter.¹ Most intracranial neoplasms also exhibit "contrast enhancement" in all or part. The presence, extent, and pattern of tumor contrast enhancement has proved to be of significant value in improving the detection, localization, and characterization of intracranial neoplasms by CT^{16, 53} and MRI.¹⁰⁰

Although the passage of *intravascular* contrast agent through brain parenchyma causes brief transient enhancement of the normal cerebral cortex,^{1, 112} leakage of contrast material into the *extravascular* extracellular space accounts for the more pronounced and somewhat longer lasting contrast enhancement seen in many tumors and other structural abnormalities of the brain on both CT^{51, 53} and MRI.¹ The mechanisms involved in contrast enhancement of intracranial neoplasms on CT and MRI and in the uptake of radionuclide by such tumors appear to be identical.^{10, 53, 103, 112}

In normal brain, tight intercellular junctions between capillary endothelial cells create a "blood-brain barrier" that prevents escape of radionuclide or contrast agent from the intravascular space. In gliomas, electron microscopic studies have demonstrated that the endothelial junctions are frequently patent and that the level of junctional patency is proportional to the degree of tumor malignancy.¹⁹⁸ It therefore seems reasonable to postulate that the intensity of contrast enhancement in gliomas and other intracranial tumors reflects the degree of blood-brain barrier breakdown.^{51, 53, 236, 289} Experimental data support this hypothesis by demonstrating that the peak intensity of tumor contrast enhancement in malignant gliomas occurs 20 to 60 minutes later than the peak serum concentration of contrast agent.^{236, 293} Furthermore, glucocorticoids, which are known to diminish defects in the blood-brain barrier, also significantly reduce the extent of contrast enhancement in primary and secondary brain tumors.^{75, 86, 134}

Factors involved in maximizing contrast enhancement of intracranial neoplasms on CT or MRI include the quantity of injected contrast agent and the timing of the images. Conventional protocols for IV administration of contrast media for CT use 28 to 42 grams of iodine (100 to 150 mL of 60% iodine concentration injected as a bolus or 200 to 300 mL of 30% iodine concentration delivered as an infusion). Doubling of the dose of contrast material has been reported to significantly increase the incidence, extent, and intensity of contrast enhancement in both gliomas and metastases on CT images obtained 60 to 90 minutes after injection,^{137, 294, 299} without permanent alteration of serum creatinine levels.¹³⁶ Not only are more lesions identified with this delayed double dose technique but also hypodense centers within "ring" lesions have been observed to gradually opacify.^{236, 294} Because of the potential for permanent renal damage with such high doses of iodinated contrast agents and because the serum creatinine concentration does not assay all aspects of renal function, use of this double dose technique should be restricted to situations in which the clinical suspicion of one or more focal lesions is high

and results of previous studies have been equivocal or negative.

The standard dose of paramagnetic contrast agent (typically a chelate of gadolinium) administered intravenously for MRI is 0.1 millimoles per kilogram of body weight.¹⁰⁰ In a comparative study, the sensitivity of contrast enhanced MRI using conventional single dose technique for the detection of cerebral metastases exceeded that of contrast enhanced CT, even with double dose of contrast material and delayed imaging.⁸²

The diagnostic efficacy of a double dose of gadolinium (0.2 mmol/kg) has been open to question, and few centers currently use it. A triple dose (0.3 mmol/kg) has also been advocated, with some evidence that its use demonstrates more lesions in the brain.^{135, 359}

Contrast enhancement on MRI is usually assessed on T1-weighted images obtained with fat saturation. However, enhancement is also demonstrated on T2-weighted images obtained with fluid attenuated inversion recovery (FLAIR); this latter technique has proved to be advantageous in the evaluation of peripherally located superficial lesions of the brain and in meningeal disease.²¹¹

Application of a strong radiofrequency pulse that is slightly offset from the resonance frequency of water protons before initiation of the standard T1-weighted spin-echo pulsing sequence produces saturation of protons in macromolecules, which is then transferred to the free water protons, thus diminishing their signal intensity. Because this maneuver does not affect the T1 shortening caused by IV administration of gadolinium, the intensity and conspicuity of resultant contrast enhancement are increased.¹⁰⁵ This phenomenon is known as *magnetization transfer* (MT), and its application in brain tumor MRI has been judged as equivalent to the improvement gained with administration of high doses of gadolinium.¹ However, because of greater suppression of white matter signal, magnetization transfer alters tissue contrast relationships such that certain structures (basal ganglia, pulvinar, substantia nigra) become more conspicuous on noncontrast MT images, whereas other structures that normally enhance (choroid plexus, cerebral veins and dural venous sinuses, body of caudate nucleus, pituitary gland) do so more conspicuously on MT images acquired after contrast administration.¹ The reader must therefore exercise caution in interpreting areas of apparent contrast enhancement as possibly signifying disease.

Newer Diagnostic Techniques

Accumulated experience together with continuing improvements in contrast discrimination and spatial resolution have permitted highly accurate correlation between CT and MRI appearance and histologic grading of supratentorial gliomas.^{10, 51, 84, 191, 276} However, noninvasive differentiation between high grade glioma with a cystic or necrotic center, solitary metastatic carcinoma with central necrosis, resolving hematoma, resolving infarction, atypical masslike presentation of a tumefactive multiple sclerosis plaque, and cerebral abscess on the basis of CT or MRI findings remains a difficult task.^{5, 38, 348} Also, precise and accurate

separation of infiltrating high grade glioma from surrounding edema is not currently attainable with either conventional MRI or CT, even after IV administration of contrast medium.^{45, 95} Differentiation between recurrent tumor and radiation necrosis is another major diagnostic problem in the management of the patient with malignant glioma who has already undergone surgical resection with postoperative radiation therapy.⁸⁹ Newer diagnostic techniques based on magnetic resonance are addressing these problems (see later).^{23, 183}

Magnetic Resonance Spectroscopy (MRS)

In magnetic resonance spectroscopy (MRS), the resonance signal that is utilized to generate an image in MRI is instead used to generate a frequency spectrum reflecting the components that make up that image.¹⁷⁹ In normal brain tissue, these components reflect both the water content of the brain and the metabolism of the normal neurons and glial cells. If the signal from water is suppressed, the frequency spectrum (expressed in parts per million [ppm]) reflects the cellular metabolism of the brain in the voxel or section of tissue being interrogated.

The highest peak amplitude in the normal brain frequency spectrum is that of *N*-acetyl aspartate (NAA), which occurs at a frequency of 2.0 ppm. NAA is a specific marker of neuronal density and viability. The next highest peak in the normal brain spectrum is that of creatine (Cr), at 3.03 ppm; creatine is involved in energy dependent processes of cellular metabolism in many different types of cells. The third highest peak of the normal brain spectrum is that of choline (Cho), which is involved in and reflects the metabolism of cellular membrane turnover; its frequency peak is 3.2 ppm. In normal brain, the ratio of the height of the choline peak to that of the creatine peak (Cho/Cr) is less than 1.0.

Another important metabolite peak occurs at approximately 1.32 ppm and reflects both lipids and lactate. Lactate is not a normal constituent of brain metabolism; its presence indicates that the normal cellular oxidative metabolism has been altered and that glycolysis is taking place via anaerobic pathways. An elevated lactate peak is seen in the presence of cellular necrosis and reflects lesions that have outgrown their blood supply—for example, the central portions of abscesses, malignant gliomas, lymphomas, and carcinomatous metastases. Lipids resonate at a similar frequency and are also found in highly malignant tumors.⁶⁰

When the interrogating voxel is placed on the peripheral contrast enhancing rim of a rounded intracerebral mass with central hypointensity on T1-weighted MRI, the MR spectroscopic pattern demonstrating elevation of the choline peak with depression of the NAA and creatine peaks is typical for both primary and secondary malignant tumors of the brain and does not aid in their differentiation (see Fig. 5-14B).^{60, 262} MRS of the central hypointense region of such a mass demonstrates elevated lactate and lipid signals, which indicate only the presence of necrosis and do not provide differential information. However, the choline peak in peripheral viable tissue is not elevated in inflammatory processes such as fungal, parasitic, and bacte-

rial abscesses, possibly representing an important differential finding.^{131, 262}

It is clearly established that in malignant gliomas, infiltrating tumor cells are present well beyond the contrast enhancing tumor margins seen on CT scans and MR images.^{45, 49} However, in metastasis, the peritumoral region contains no infiltrating tumor cells.⁴⁹ Studies involving MR spectroscopic interrogation of the peritumoral region in patients with solitary brain tumors have documented elevated choline levels with reversal of the normal Cho/Cr ratio in the peritumoral region in patients who have infiltrating high grade gliomas but not in patients who have metastases.^{23, 183} This finding on MRS may enable the discrimination between malignant glioma and metastasis and suggests that the peritumoral hyperintensity on T2-weighted images and the peritumoral hypointensity on T1-weighted images seen in association with malignant gliomas may reflect not only vasogenic edema (see later) but also tumor infiltration, whereas the lack of reversal of the Cho/Cr ratio in the peritumoral tissue surrounding metastases suggests that the similar MRI appearance of this tissue is likely due to edema or gliosis.¹⁸³

Perfusion-Weighted MRI

Another difference between patients with malignant glioma and those with metastasis has been noted on dynamic contrast enhanced perfusion-weighted MRI utilizing a first pass image acquisition protocol after bolus IV administration of gadolinium.¹⁸³ One study has demonstrated a significant increase in relative cerebral volume (rCBV) in the peritumoral region in patients with malignant gliomas, and a diminished rCBV in the peritumoral region in patients with metastases.¹⁸³ Increased peritumoral perfusion in patients with malignant gliomas is presumed to be due to tumor infiltration into the peritumoral region with associated loss of blood-brain barrier integrity. Diminished peritumoral perfusion in the tissue surrounding a metastasis may reflect an intact blood-brain barrier with the vasogenic edema causing local compression of the microcirculation.¹⁸³

Positron Emission Tomography

Studies of cerebral oxygen metabolism using the positron-emitting isotope fluorine-18 (¹⁸F) tagged to fluoro-deoxyglucose (FDG), an analogue of glucose, have established that most malignant brain tumors have increased glucose uptake and metabolism compared with normal brain parenchyma,⁸⁸ that the level of ¹⁸FDG uptake correlates well with histologic grade in cerebral gliomas,⁸⁸ and that ¹⁸FDG positron emission tomography (PET) is a good predictor of prognosis in these tumors.¹⁷

Differentiation between recurrent tumor and radiation necrosis remains a major unsolved problem in the management of patients with malignant gliomas.⁸⁹ Both processes can present the heterogeneous appearance of a growing infiltrative mass with irregularly marginated contrast enhancement on CT and MRI. Early work suggested that necrotic tissue failed to take up the radioactivity and appeared hypometabolic and that actively growing tumor demonstrated strong hypermetabolic uptake.⁸⁹ This finding was verified on a subsequent study demonstrating high sensitivity and specificity for ¹⁸FDG PET.¹⁶¹ However, other

studies have questioned the accuracy and specificity, and therefore the utility, of ^{18}F FDG PET for this indication.²⁷⁵

Complications of Brain Tumors

Brain Edema

Edema or swelling of the brain is a common accompaniment of many brain tumors and other structural abnormalities of the brain. When sufficiently severe, edema may be responsible for both focal and generalized signs of brain dysfunction.^{106, 286} Edema is not a single pathologic response to a variety of insults but rather occurs in at least three different forms,¹⁶² vasogenic (secondary to tumor, inflammation, hemorrhage, extensive infarction, or contusion), cytotoxic (in response to hypoxia, early infarction, or water intoxication), and interstitial (resulting from acute obstruction to the flow or absorption of cerebrospinal fluid [CSF]).

Vasogenic edema is the form of brain swelling most typically associated with intracranial neoplasms. It is caused by a breakdown in the blood-brain barrier with seepage of a plasma filtrate containing plasma proteins through patent junctions between capillary endothelial cells.¹⁰⁶ Gray matter is relatively resistant to the development of edema, and the extracellular plasma filtrate mainly accumulates in the white matter, extending along the major white matter fiber tracts. The subcortical arcuate (U) fibers between adjacent gyri offer greater resistance to the spread of edema than the long white matter tracts and are therefore involved relatively later and in more severe cases.

The severity of edema associated with various brain tumors varies widely, even between lesions of identical histology. In general, white matter swelling is greatest in association with carcinomatous metastases, and it is not unusual for a small metastasis to provoke a disproportionately large amount of edema.^{286, 364} In order of declining severity, edema is associated with metastases, glioblastomas, meningiomas, and low grade gliomas, but exceptions to this order are common.²¹⁹ Rarely, a low grade glioma may be surrounded by extensive edema, whereas occasional metastases or meningiomas may have little associated white matter swelling.

On CT, vasogenic edema appears as widening and diminished density of the major white matter tracts with finger-like extensions into the arcuate fibers in each gyrus.^{94, 219} The overlying cortical gray matter is compressed and thinned by the expanded pseudopods of edematous white matter (see Figs. 5-12 and 5-17).

On noncontrast enhanced MRI, the high water content in the edematous peritumoral white matter causes prolonged T1 and T2 relaxation in the involved white matter; these findings manifest as an increase in signal intensity on T2-weighted images and as a less conspicuous decrease in signal intensity on T1-weighted images (see Figs. 5-1A, 5-13, 5-20B).¹⁷⁵ It is often difficult to delineate the boundary between tumor and edema on these nonenhanced images; IV administration of paramagnetic contrast agent permits gross demarcation on T1-weighted (see Fig. 5-20C) and FLAIR images in many tumors (e.g., metastases) but not in malignant gliomas, as noted previously.^{45, 95}

Systemic administration of glucocorticoids minimizes

the blood-brain barrier defect inherent in most higher grade brain tumors, with resultant reduction in fluid and protein extravasation. Diminution in peritumoral white matter swelling as well as in the volume and intensity of tumor contrast enhancement is often evident on followup imaging studies within a few days after institution of steroid therapy.^{75, 134}

Interstitial edema secondary to obstruction of CSF pathways appears on CT as poorly circumscribed periventricular hypodensity⁹⁴ and on T2-weighted MRI as bandlike periventricular hyperintensity of varying thickness and margination.^{175, 374} These findings are often symmetrical and are most evident surrounding the anterosuperior margins of the dilated frontal horns of the lateral ventricles (see Fig. 5-2D) and the posterior margins of the occipital horns.¹⁷⁵ Fluid accumulates in the periventricular white matter as a result of transependymal seepage of ventricular fluid across microscopic breaks in the ependymal lining of the ventricles. Systemic glucocorticoids do not affect this type of edema, but surgical insertion of a shunt catheter above the level of obstruction usually results in prompt decompression of the ventricles and disappearance of the periventricular hypodensity/hyperintensity.⁹⁴

Herniations

An expanding mass within the rigid cranial vault, whether due to tumor, edema, or a combination of both processes, compresses and distorts the adjacent normal brain, producing internal herniation of the brain under the relatively rigid falx or through the tentorial incisura.

Laterally placed masses in the cerebral hemispheres, particularly those located in the superior temporal, midfrontal, or frontoparietal regions, displace the deep central structures (basal ganglia, thalamus, third ventricle, lateral ventricles, septum pellucidum) medially.²⁸⁰ The ipsilateral cingulate gyrus is compressed and displaced across the midline under the free edge of the falx (*subfalcine herniation*). Medially located high frontoparietal (parasagittal) masses depress and also displace the cingulate gyrus contralaterally but without significantly affecting the deep central structures. Subfalcine herniation is most clearly depicted on coronal CT scans and MR images, which also demonstrate depression and contralateral displacement of the corpus callosum and the underlying body of the ipsilateral ventricle (Fig. 5-1). The septum pellucidum and third ventricle are bowed away from the side of the mass. On axial CT scans and MR images, the ipsilateral ventricle appears compressed and displaced contralaterally.

Tumors of the temporal lobe and middle cranial fossa displace the uncus and parahippocampal gyrus on the medial aspect of the temporal lobe toward the midline, with resultant encroachment on the lateral aspect of the suprasellar and ambient (circummesencephalic) cisterns and the tentorial incisura (*descending transtentorial herniation*) (see Figs. 5-7 and 5-18A).^{280, 286, 331} The ipsilateral margin of the midbrain is compressed, displaced contralaterally, and rotated by the impinging temporal lobe. Noncontrast MRI, contrast enhanced CT, or both may demonstrate medial displacement of the posterior communicating and posterior cerebral arteries, narrowing of the contralateral crural

Figure 5-1. Right high frontal convexity meningioma causing subfascial herniation. **A**, Axial T1-weighted noncontrast MR image at the level of the cingulate gyri. The right cingulate gyrus is displaced to the left of the midline under the free edge of the falx cerebri by a large lobulated rounded heterogeneous hypo- and isointense parasagittal mass (arrow). Note that the mass is surrounded by focal signal voids representing enlarged vessels on the surface of this extraaxial tumor. A wide band of slight hypointensity surrounding the mass represents vasogenic edema of the peritumoral white and gray matter. **B**, Coronal T1-weighted postintra-venous gadolinium image through the level of the mid third ventricle demonstrates marked downward and medial displacement of the right side of the corpus callosum and the frontal horn of the right lateral ventricle. The third ventricle (arrow) is bent and displaced across the midline by this large homogeneously contrast enhancing dural based tumor.

and circummesencephalic cisterns, and widening of their ipsilateral counterparts behind the impinging temporal lobe.³¹² Late secondary signs include hemorrhages in the compressed midbrain and unilateral or bilateral medial occipital infarctions (due to occlusion of one or both posterior cerebral arteries).^{286, 312} Large centrally located cerebral masses for which the primary vector of force is directly downward may cause bilateral transtentorial herniation.

Ascending transtentorial herniation with upward displacement of the superior cerebellar vermis through the posterior aspect of the tentorial incisura is caused by expanding masses in the superior portion of the posterior compartment of the posterior cranial fossa, including the upper half of the cerebellum.²⁸⁶ As the superior cerebellar vermis is forced anteriorly and superiorly into the incisura, it protrudes into and compresses the superior cerebellar cistern from below and flattens the normal posterior convexity of the quadrigeminal cistern from behind.²³⁹ Increasing severity of herniation leads to reversal of that convexity and eventually to obliteration of the quadrigeminal and superior cerebellar cisterns (Fig. 5-2A and B) with flattening of the posterior margin of the third ventricle.

Tumors of the lower half of the cerebellum and other masses in the inferior portion of the posterior compartment of the posterior fossa may produce downward displacement of the cerebellar tonsils through the foramen magnum (*tonsillar herniation*).²⁸⁶ This situation can be visualized directly on T1-weighted MRI in the sagittal plane (see Fig. 5-2A and C) and can be suggested on axial CT or MRI if the cisterna magna and upper cervical posterior subarach-

noid spaces are encroached on and partially or completely obliterated by soft tissue density.

Hemorrhage

Hemorrhage is not a common accompaniment of most intracranial neoplasms at initial presentation. In a series of 973 intracranial tumors, CT demonstrated acute intratumoral bleeding in 28 patients (3%) at the time of initial diagnosis and in 7 additional patients (0.7%) who experienced clinical deterioration during their subsequent course.³⁶⁹ In Cushing and Eisenhardt's⁷⁸ meticulously reported experience, hemorrhage was found in association with intracranial gliomas in 31 of 832 cases (3.7%). Acute hemorrhage was demonstrated on CT in 6 of a series of 131 meningiomas (4.6%).²⁸⁷

Intratumoral bleeding is more common in certain tumors, notably metastases from choriocarcinoma, melanoma (see Fig. 5-62), carcinomas of the lung and thyroid, and renal cell carcinoma,^{12, 205} as well as in neuroblastoma, lymphoma, and medulloblastoma.³⁶² In metastatic melanoma and choriocarcinoma, the typically hyperdense appearance of the metastatic nodules on CT has been attributed to the presence of acute hemorrhage or hemosiderin within the tumor.¹¹⁶

Because many of the breakdown products of blood have paramagnetic properties, MRI provides a unique and highly sensitive method for detection of subacute or chronic intracranial bleeding.^{12, 122} Hemorrhage associated with intra-

cranial tumors may occur centrally within a necrotic tumor cavity (in glioblastoma [see Fig. 5-12] and some metastases) or peripherally around the tumor (seen in other metastases and meningiomas). Signal intensity (MR) or density (CT) is typically more heterogeneous in tumor bleeds than in benign intracranial hemorrhage.^{9, 12} On occasion, hemorrhage may completely mask the presence of the underlying neoplasm, but images obtained after injection of contrast medium may demonstrate enhancement of tumor along a margin of the hematoma or in other locations within the brain.^{10, 369} Hemorrhage into a pituitary adenoma is a common cause of "pituitary apoplexy" and may obliterate not only the entire tumor but also the normal pituitary (see Figs. 5-55 and 5-56).^{267, 316} Intracranial hemorrhage not related to underlying tumor may occur in patients receiving systemic chemotherapy for acute leukemia who demonstrate bone marrow depression with low levels of circulating platelets.²⁴⁶

Resolution and organization of acute intratumoral and peritumoral hematomas are often somewhat delayed in comparison with those of other intracranial hematomas.^{9, 10} In fact, high signal intensity on T1- and T2-weighted MR images in an area of parenchymal hemorrhage that persists beyond the expected time of hematoma resolution should raise the possibility that the hemorrhage has occurred within tumor tissue.¹⁰ It is probable that atypical hypodense regions on CT within some meningiomas and pituitary adenomas represent foci of necrosis or cystic change secondary to old hemorrhage.^{267, 287}

Gliomas

Gliomas represent 40% to 45% of all intracranial tumors.^{286, 344} They include all primary brain tumors of astrocytic, oligodendroglial, or ependymal origin—astrocytomas, oligodendrogliomas, and ependymomas as well as choroid plexus papillomas and carcinomas.

Astrocytomas

Astrocytomas (tumors derived from astrocytes) are the most common of all primary intracranial neoplasms.³⁰³ They account for approximately 60% of all primary tumors of the brain.⁶¹ In the 1993 revision of the WHO classification of brain neoplasms, astrocytomas were subdivided into four histologic grades.¹⁶³ This histologic grading system has demonstrated a high positive correlation with the biologic potential and behavior of tumors. Tumors of lower histologic grades (I and II) demonstrate few mitoses, little cellular structural variation (pleomorphism), and no vascular proliferation or necrosis. Tumors in grades III (anaplastic astrocytoma) and IV (glioblastoma multiforme) are characterized by more frequent mitoses, higher degrees of cellular dedifferentiation, and increasing angiogenesis at the tumor periphery and by necrosis within the more central portion of the tumor.

Astrocytomas are characterized on both gross dissection and diagnostic imaging into two groups, circumscribed and diffuse. Generally speaking, the diffuse astrocytomas are more common, tend to occur more in adulthood, and are

more infiltrative or aggressive with spread along the white matter tracts.⁶¹

Circumscribed Astrocytomas

Three histologic types of astrocytoma are assigned to the circumscribed group. They are the juvenile pilocytic astrocytoma (JPA), the pleomorphic xanthoastrocytoma (PXA), and the subependymal giant cell astrocytoma (SCGA).^{47, 303} All three types occur mainly in children and have a less aggressive biologic potential than the diffuse astrocytomas.

Juvenile Pilocytic Astrocytoma. The most common type of circumscribed astrocytoma, JPA represents 2% to 6% of all primary brain tumors.³⁰³ It most commonly (60% of cases) occurs in the cerebellum (hemispheres more often than vermis) in children (Figs. 5-2 and 5-3), with a peak age distribution between 5 and 15 years. JPA is also frequently found, however, in the intracranial optic nerves and chiasm and the adjacent hypothalami (Fig. 5-4), usually in slightly younger children (2 to 3 years) and often in association with neurofibromatosis type I (NF1, also known as von Recklinghausen's disease).^{6, 47, 303}

JPA is the classic well circumscribed brain neoplasm, but it lacks a true tumor capsule. It grows mainly by expansion rather than by infiltration. It is widely considered to be a benign (biologically stable) neoplasm and is classified as histologic grade I.⁴⁷ It may be densely cellular or more loosely arranged with intervening microcysts, and both patterns may coexist in different portions of the same tumor. Mitoses are rare in this lesion, and necrosis is not seen. Most often, the tumor represents a mural nodule in the wall of a well circumscribed cyst. The origin and nature of the cyst are not well understood, but the cyst fluid is proteinaceous and is probably secreted from coiled capillaries found in the midst of the nodular tumor. With the exception of the mural tumor nodule, the wall of the cyst consists of compacted normal brain or nonneoplastic gliotic tissue.⁴⁷ Intratumoral calcification is occasionally identified (5% to 25% of cases), but hemorrhage into or adjacent to the tumor is rare.³⁰³

The clinical presentation of children with JPA depends on the tumor site. The cerebellar tumors typically manifest with headache, nausea, and vomiting because of hydrocephalus secondary to obstruction of the fourth ventricle.⁵⁶ Weakness and loss of equilibrium are not uncommon. The optic tumors typically cause difficulties with vision, but signs of hydrocephalus may appear if the tumor has extended into the hypothalamus and is obstructing the third ventricle.⁶

On CT, the typical JPA appears as a smoothly marginated, hypodense cystlike mass with a well defined, less hypodense tumor nodule on one wall (see Fig. 5-3A). The nodule may contain one or more areas of dense calcification. The cyst fluid is less hypodense than the CSF (15–25 Hounsfield units [HU]) because of the high protein concentration.²²⁶ Typically, after IV administration of a contrast agent, dense homogeneous contrast enhancement of the tumor nodule, but not of the other walls of the cyst, is seen (see Fig. 5-3B, C).^{190, 200, 226} More extensive enhancement of the cyst walls suggests a more aggressive (higher histologic grade) tumor.⁵⁶

Figure 5-2. Juvenile pilocytic astrocytoma of the cerebellum causing interstitial edema and upward transtentorial herniation and tonsillar herniation. **A**, Left parasagittal T1-weighted MR image without intravenous contrast. A large sharply margined cyst in the left cerebellar hemisphere causes downward herniation of the cerebellar tonsils into the upper cervical spinal canal (*arrow*). The cystic mass compresses the fourth ventricle and pons from behind and displaces the superior vermis upward through the tentorial notch, obliterating the superior cerebellar and quadrigeminal cisterns and elevating and displacing forward the floor and posterior wall of the third ventricle. **B**, Axial T1-weighted noncontrast image at the level of the quadrigeminal cistern demonstrates forward displacement and compression of the quadrigeminal plate and cistern on the left (*arrow*) by the upwardly herniating superior cerebellar vermis and hemisphere. Note enlargement of the aqueduct, third ventricle, and temporal horns of the lateral ventricles secondary to obstruction of the fourth ventricle. **C**, Coronal T1-weighted image at the level of the posterior aspect of the foramen magnum following intravenous administration of gadolinium. Both cerebellar tonsils have herniated downward through the foramen magnum (*arrow*). Note homogeneous contrast enhancement of a solid tumor nodule in the floor of the left cerebellar hemisphere cystic mass. **D**, Axial T2-weighted image at the level of the superior aspect of the lateral ventricles. The ventricles are markedly distended, and cerebrospinal fluid has dissected across the ependymal margins of the ventricles into the adjacent periventricular white matter anteriorly (*arrow*) and in the corpus callosum.

Figure 5-3. Juvenile pilocytic astrocytoma of the cerebellum. A, Axial CT image without intravenous contrast. A large well circumscribed hypodense mass is noted in the left cerebellar hemisphere. A flat nodular density is seen on the posteromedial wall of this cystic hypodensity (arrow). Axial (B) and parasagittal (C) T1-weighted MR images following intravenous administration of gadolinium demonstrate intense homogeneous contrast enhancement of the mural nodule (arrows) within the cystic hypointense mass.

On MRI, the mural nodule appears homogeneously hyperintense to gray matter on T2-weighted images and hypointense to isointense on T1-weighted images.^{190, 200, 226} Intratumoral calcification may cause a more heterogeneous appearance. The associated cyst is even more hyperintense on T2-weighted images and even more hypointense on T1-weighted images (see Fig. 5-2A). Edema of the adjacent white matter is usually minimal. Homogeneous contrast enhancement of the tumor nodule is characteristic (see Figs. 5-2C and 5-3B and C), although a calcific focus, if present, does not demonstrate enhancement.

The clinical prognosis of JPA is guardedly optimistic. The cerebellar tumor nodule can often be totally excised,

and 5- and 10-year survival rates exceeding 75% are commonly reported.^{47, 56} The location and extent of the optic-chiasmatic-hypothalamic tumors typically preclude total excision, but irradiation and chemotherapy often achieve long-term tumor control.^{47, 368}

Pleomorphic Xanthoastrocytoma. PXA was newly designated in the 1993 WHO revised classification.^{163, 303} The number of cases documented in the literature is still small. PXA is presumed to arise from subpial astrocytes near the surface of the cerebral hemispheres.^{70, 159} Rare tumors have also been described in the posterior cranial fossa and in the spinal cord. The gross morphology resem-

Figure 5-4. Juvenile pilocytic astrocytoma of the optic chiasm and hypothalamus with spread along visual pathways. Axial T1-weighted MR images obtained with fat saturation following intravenous gadolinium. *A*, At the level of the mid orbits, arrows indicate contrast enhancement in and marked widening of the intraorbital optic nerves bilaterally due to tumor spread. *B*, At the level of the optic chiasm, note widening of the chiasm and extension of the contrast enhancing tumor into the left optic tract (arrow). *C*, At the level of the mid third ventricle, intense homogeneous contrast enhancement indicates tumor extension into the basal ganglia bilaterally (arrows).

bles the nodule and cyst appearance of the pilocytic astrocytoma. The nodule is often based on the pial surface of the brain.

On CT and on MRI, the appearance is similar to that of the pilocytic astrocytoma: well circumscribed, hypodense to isodense on CT, hypointense on T1-weighted and hyperintense on T2-weighted MR images, often with cystic component (Fig 5-5A). However, the location is supratentorial (order of descending frequency: temporal, frontal, parietal) and superficial with little or no mass effect.^{195, 333} Although the tumor presents a circumscribed appearance, it usually grows slowly and may infiltrate the overlying pia, even causing focal thickening of the meninges (dural tail). Intense homogeneous contrast enhancement of the tumor nodule is the rule (Fig. 5-5B, C).

Histologically, as the name implies, the tumor nodule is pleomorphic, but cells with a foamy myxoid cytoplasm are common.⁷⁰ PXA is usually classified as grade II, but later dedifferentiation into higher grade neoplasm may occur.^{70, 159} The clinical presentation most commonly consists of seizures that may be intractable. Most reported cases have been in adolescents or young adults; the median age at diagnosis is 14 years.³⁰³

Subependymal Giant Cell Astrocytoma. This low-grade (WHO grade I) astrocytic tumor occurs almost exclusively in patients with tuberous sclerosis in their late teens or 20s.²⁹⁸ It is estimated that 10% to 15% of patients with tuberous sclerosis develop this grade I neoplasm.^{301, 303} These tumors arise from subependymal nodules located on

Figure 5-5. Pleomorphic xanthoastrocytoma of the left frontal convexity. A, Coronal turboFLAIR MR image displays a semilunar hyperintense bandlike lesion indenting the left frontal convexity (arrow). More superficially, the mass appears hypointense and mushrooms outward, eroding the calvarium and bulging into the overlying scalp. T1-weighted coronal (B) and parasagittal (C) images following intravenous gadolinium demonstrate contrast enhancement of the mural nodule (arrows). The findings suggest a superficial cystic tumor with mural nodule of long standing.

the lateral wall of the lateral ventricle overlying the head of the caudate nucleus.^{298, 349} By convention, subependymal nodules that are more than 1 cm in diameter or that become symptomatic are considered giant cell astrocytomas.³⁴⁹ The tumor does not invade into the underlying caudate head but rather grows outward into the ventricular lumen near the foramen of Monro, which may be obstructed either unilaterally or bilaterally. Despite this tendency for intraventricular growth, the overlying ependyma remains intact, and dissemination via the CSF is rare.³⁰³ Intratumoral calcification is common and may be heavy.

Histologically, the tumor is seen to contain large multinucleated giant cells of uncertain origin.^{25, 349} On cytochemical analysis, some of these cells display GFAP (glial fibrillary acidic protein) reactivity, a feature consistent with an astrocytic origin, whereas others contain neuron-specific enolase, a finding consistent with neuronal origin.²⁵

Subependymal giant cell astrocytomas present a charac-

teristic appearance on CT.^{200, 226, 303} They appear as large, hypodense, polypoid, sharply margined intraventricular masses at the level of the foramen of Monro (Fig. 5-6A). The tumor may be heavily calcified and may obstruct the foramen unilaterally or bilaterally, causing gross enlargement of one or both lateral ventricles. Other manifestations of tuberous sclerosis are usually evident, including cortical tubers and subependymal hamartomatous nodules.²²⁶ On MRI, subependymal giant cell astrocytoma appears as a heterogenous, sharply demarcated intraventricular mass that is mildly hyperintense on T2-weighted images and hypointense or isointense on T1-weighted images. It is located within the frontal horn of the left ventricle without evidence for deep invasion or spread within the basal ganglia.^{200, 303} On both CT and MRI, intense but heterogeneous contrast enhancement is often demonstrated (Fig. 5-6B). The heterogeneous signal on MRI both with and without contrast enhancement reflects the presence of dense

Figure 5-6. Subependymal giant cell astrocytoma in a patient with tuberous sclerosis. Axial CT images prior to (A) and following (B) intravenous administration of iodinated contrast medium. A partially calcified (arrow in A) multilobulated mass arising on the medial surface of the head of the right caudate nucleus fills and obscures the frontal horn of the right lateral ventricle. On the left, a calcified tuber (not neoplastic) obstructs the foramen of Monro; the dilated left frontal horn is compressed and displaced by a cyst, which is likely secondary to previous ventriculostomy complication. The noncalcified portion of the right frontal intraventricular tumor demonstrates homogeneous contrast enhancement (arrow in B).

calcification in these tumors. Differentiation of this tumor from the subependymal hamartomatous nodules that are so ubiquitous in patients with tuberous sclerosis is sometimes problematic, but the factors usually considered are the characteristic tumor location, its larger size, and the presence of contrast enhancement (not seen in the nontumorous nodules).^{200, 303}

Diffuse Astrocytomas

Poorly margined diffuse astrocytomas demonstrate much more aggressive infiltrative behavior than circumscribed astrocytomas. Progression from lower histologic grade (astrocytoma, WHO grade II) to higher grades (anaplastic astrocytoma, WHO grade III; glioblastoma multiforme, WHO grade IV) is common.^{286, 303}

Low Grade Astrocytoma. Low grade (WHO grade II) supratentorial astrocytomas are hypercellular tumors that demonstrate few mitoses and moderate pleomorphism but no vascular proliferation or necrosis.^{61, 165} On immunohistochemistry studies, they demonstrate strong affinity for GFAP.¹⁶⁵ These tumors, often simply labeled astrocytomas without any modifier, constitute 10% of all intracranial tumors and 15% to 20% of all gliomas.^{191, 303, 342, 345} They arise in white matter and grow by infiltration, predominantly along white matter tracts, extending between and separating anatomic landmarks. The involved area of the brain eventually appears larger than its contralateral counterpart. Cerebral astrocytomas are usually solid masses

that, because of their infiltrative characteristics, are poorly circumscribed and blend imperceptibly with the adjacent cerebral parenchyma. Small and large cysts are occasionally found within these tumors,²⁸⁶ but hemorrhage is rare.

Low grade astrocytomas arise mainly in the frontal, parietal, and temporal lobes (Fig. 5-7). They typically provoke little or no edema in the surrounding tissues. Because such a tumor begins in the white matter without affecting the more eloquent cortical centers, symptoms are usually vague and nonlocalizing until the lesion gains sufficient size, extends into eloquent cortex, or undergoes dedifferentiation into a grade III or IV tumor.³⁰⁴ The peak age range for occurrence of low grade astrocytoma is the third through fifth decades of life.

Some diffuse (initially low grade) astrocytomas occur in childhood, notably involving the optic nerves and chiasm, optic tracts, and visual pathways as well as the hypothalamus and thalamus. More than half of the optic pathway gliomas of early childhood involve the optic chiasm and hypothalamus, and 40% of these are diffuse fibrillary astrocytomas.⁴ In contradistinction to the young children with neurofibromatosis type I in whom more circumscribed pilocytic astrocytomas of the visual pathways develop,⁶ the more solid and diffuse astrocytomas arise in a similar age group (peak age 2 to 3 years) but without any identifiable genetic predilection.⁶¹ However, the diffuse fibrillary tumors share with their adult counterparts a more aggressive biologic progression and thus merit a more aggressive course of management.⁴

Figure 5-7. Low grade astrocytoma of the temporal lobe. Axial T1-weighted MR images prior to (A) and following (B) intravenous administration of gadolinium. A mostly ill defined homogeneously hypointense mass expands the left anterior temporal lobe (arrow). There is no contrast enhancement and no surrounding edema. Note medial displacement of the medial margin (uncus and parahippocampal gyrus) of the left temporal lobe indicating early transtentorial herniation with compression of the left ambient cistern and the anterolateral aspect of the left cerebral peduncle.

Another relatively common location of diffuse low grade astrocytoma in childhood is in the brain stem. Brain stem gliomas constitute 10% to 20% of all pediatric brain tumors.²⁰⁰ The peak age of occurrence is 5 to 10 years. These tumors arise mainly in the pons but commonly involve the midbrain and medulla.³⁶⁶ Despite their proximity to the aqueduct and fourth ventricle, considerable tumor growth may take place without causing obstruction of the ventricular system. Cranial nerve deficits, long tract signs, and ataxia are the most common presenting findings.^{200, 206, 366} Although these tumors are often regarded as low grade lesions, histologic heterogeneity with intermixed areas of higher grade neoplastic change is common.³ Approximately 60% demonstrate foci of glioblastomatous change with central necrosis.²⁸⁶ Five year survival rates range from 15% to 30%.²⁰⁰

On CT scans, low grade diffuse cerebral astrocytomas appear most commonly as poorly margined areas of decreased attenuation involving the white matter of one or more lobes of the brain with mild to moderate mass effect.^{53, 191, 208, 275, 303} A more heterogeneous appearance with patchy areas of normal or slightly higher tissue density intermixed with hypodensity is seen in a small number of cases. Contrast enhancement is usually absent, reflecting a lack of tumor vascularity, blood-brain barrier breakdown, or both.³⁰³

Because low grade astrocytomas are predominantly hypodense (15 to 30 HU) and usually do not exhibit contrast enhancement, it is often not possible to differentiate the

margin of the tumor from the adjacent white matter with CT. However, because the blood-brain barrier is intact, extensive peritumoral edema is unusual in low grade astrocytomas.^{5, 191, 303} Grossly identifiable areas of intratumoral hemorrhage or necrosis are also not seen on CT or MRI studies in these lesions. Calcification is identified in 20% of these tumors, and cysts are occasionally demonstrated.²⁷⁵ The presence of hemorrhage, necrosis, edema, and/or contrast enhancement suggests progression to a higher tumor grade.

Optic chiasm-hypothalamic diffuse astrocytomas appear on CT as rounded or lobulated thickening of the optic chiasm that appears homogeneously hypodense; the tumor may encase the arteries of the circle of Willis and invade the floor of the third ventricle, causing obstructive hydrocephalus.^{4, 165, 303} Necrosis and hemorrhage are uncommon; the demonstration of contrast enhancement in these solid tumors suggests a transition to a higher tumor grade.

Brain stem gliomas typically appear on CT as ill defined diffuse heterogeneously hypodense and isodense expansions of the pons and medulla with dorsal displacement of the floor of the fourth ventricle and aqueduct and ventral encroachment upon the pontine cistern (Fig. 5-8A, B).^{3, 28, 303, 366} Despite the impression of the tumor on the aqueduct and the floor of the fourth ventricle, hydrocephalus is a relatively late finding. Approximately 50% of brain stem gliomas exhibit some contrast enhancement on CT and MRI after IV administration of contrast medium (Fig. 5-8C). Enhancement is usually patchy and heterogeneous.^{28, 197}

Figure 5-8. Brain stem glioma. Axial T2-weighted (A) and T1-weighted (B) noncontrast MR images through the midpons demonstrate a poorly circumscribed mass with heterogeneous signal intensity involving the pons, which is larger on the left than on the right (arrows). This expansile and invasive tumor causes thinning of the prepontine cistern and flattening and posterior displacement of the floor of the fourth ventricle. C, On this midsagittal T1-weighted image following intravenous gadolinium, note the extension of the tumor (arrow) superiorly into the midbrain with posterior bowing of the aqueduct and floor of the fourth ventricle and patchy intratumoral contrast enhancement.

On MR images, diffuse low grade astrocytomas appear relatively homogeneous and demonstrate varying degrees of prolonged T1 and T2 relaxation. They therefore appear homogeneously hypointense on T1-weighted images and hyperintense on T2-weighted images in comparison with normal brain (see Figs. 5-7A and 5-8A, B).^{10, 95, 275} Because of the inherently higher contrast resolution of MRI, astrocytomas are often better demarcated from adjacent normal white matter on MRI than on CT, reflecting their higher water content. Nevertheless, as on CT, the apparent margins of the lesion on the MRI (with or without contrast enhancement) do not closely correlate with histopathologic evidence of tumor extent.^{95, 175} As on CT, contrast enhance-

ment on MRI is absent in diffuse low grade cerebral astrocytomas (Fig. 5-7B); the demonstration of contrast enhancement should raise the strong suspicion of a higher tumor grade.^{51, 100, 125, 275, 303}

The differential imaging diagnosis of low grade diffuse astrocytoma on CT and MRI is ubiquitous. Principal considerations are cerebral infarction, cerebritis, and higher grade gliomas (e.g., anaplastic astrocytoma). Infarctions generally (but not always) have less mass effect, tend to involve adjacent cortical gray matter more extensively, and are often more sharply delineated from the adjacent cerebral parenchyma.²¹⁹ Inflammatory processes and higher grade gliomas are often associated with blood-brain barrier

breakdown and exhibit contrast enhancement and surrounding edema.²⁷⁵

The prognosis in low grade astrocytoma is guarded. Most of these tumors in young adults progress to a higher grade.²¹³ Median survival has been reported as 5 to 8 years.^{213, 275}

Anaplastic Astrocytoma. As the name implies, anaplastic astrocytomas (WHO grade III) exhibit considerable variation in cellular morphology, with high cellularity, frequent mitoses, and foci of vascular proliferation, findings that are not present in low grade (grade II) astrocytomas.³⁰³ However, no necrosis is present in anaplastic astrocytomas, on either gross inspection or microscopic evaluation.²⁷⁵ These tumors tend to occur in a slightly older age group (peak age mid-40s) than the grade II lesions and, in many cases (some estimates are as high as 75%), represent a progressive dedifferentiation of a previously low grade tumor.²⁴⁷

Reflecting the increased histologic variation, the imaging findings are also less homogeneous than in the lower grade tumors (Fig. 5-9A). On T2-weighted MRI, anaplastic astrocytomas are most often heterogeneously hyperintense and are associated with a greater degree of vasogenic edema and overall mass effect. Contrast enhancement on both CT and T1-weighted MRI is common (Fig. 5-9B);

compared with glioblastoma (grade IV), the enhancement pattern is not ringlike but, rather, more patchy.

Current estimates indicate that anaplastic astrocytomas represent about 25% of all primary gliomas of the brain.²⁴⁰ Median survival for patients with anaplastic astrocytoma is 2 to 3 years. Most tumors progress relatively rapidly to frank glioblastoma with intratumoral necrosis.

Glioblastoma Multiforme. Glioblastoma multiforme (WHO grade IV) is the most common primary tumor of the CNS, accounting for more than half of all intracranial gliomas.³⁴² It is biologically the most aggressive of the gliomas, with rapid progression of clinical signs and symptoms and a mean survival time in the range of 12 months. Like all other astrocytomas, glioblastoma characteristically involves the cerebral white matter, but this highly malignant process readily infiltrates and destroys the gray matter with loss of gray-white differentiation.²⁸⁶ As their name implies, these highly malignant tumors have a variegated histologic appearance, with interspersed areas of hypercellularity, cellular pleomorphism, endothelial proliferation, and intratumoral necrosis.⁴⁹

It is probable that most glioblastomas arise by anaplastic change within preexisting low grade cerebral astrocytomas, although some likely occur *de novo*.²⁸⁶ Although most commonly focal and singular in their presentation, glioblas-

Figure 5-9. Anaplastic astrocytoma, left frontotemporal. Axial CT images prior to (A) and following (B) the intravenous administration of iodinated contrast medium. On the noncontrast image (A), patchy areas of hyperdensity (arrows) are noted on both sides of the left sylvian fissure, involving the medial (insular) and lateral (temporal) aspects. There is mild mass effect on the lateral margin of the atrium of the left lateral ventricle by the posterior extension of this tumor (posterior arrow). Note the ill defined diffuse hypodensity extending between and surrounding the hyperdense regions; this likely represents a mixture of infiltrating tumor cells and reactive edema. B, On the postcontrast image, there is diffuse contrast enhancement of the previously hyperdense regions (arrows). Note that the enhancement reaches the ependymal surface of the left atrium. There is no evidence of intratumoral necrosis.

tomas may be multifocal or multicentric in origin.²⁰ The peak age of incidence of glioblastoma is during the fifth and sixth decades of life, some 10 to 20 years later than the peak age for astrocytoma. However, glioblastoma is not rare in younger adults or even in children; of all glioblastomas, approximately 3% occur in childhood, mainly in the brain stem and cerebellum. Studies indicate that the incidence of malignant gliomas is increasing significantly in the elderly.⁸⁰

On gross inspection, glioblastomas appear more or less spherical when confined to one lobe of a cerebral hemisphere. However, these rapidly growing neoplasms invariably infiltrate into adjacent lobes, the corpus callosum ("butterfly gliomas"), and the contralateral hemisphere. Tumors that have extended widely tend to have more irregular configurations with lobulated margins. Infiltration of the ependyma of the lateral and third ventricles and penetration of the cerebral cortex with invasion of the overlying meninges occur commonly and may lead to seeding through the CSF pathways.^{214, 286} Vascular endothelial proliferation with formation of large sinusoidal channels (angioneogenesis) is a typical finding in glioblastomas, and intratumoral hemorrhage is not rare.³⁶⁶ The central portions of these tumors frequently undergo ischemic coagulative necrosis, leaving only a peripheral rim of viable tumor of variable thickness.²⁸⁶ Cysts of varying size representing the residua of central necrosis may be found within the more solid portions of many glioblastomas.

The gross pathologic findings previously described are

accurately portrayed on CT and MRI. Although smaller tumors are generally rounded, more extensive lesions have irregular configurations indicating their spread along white matter pathways and penetration into and through cerebral cortex. These tumors typically appear on CT as heterogeneous masses with irregular borders of normal or slightly increased density intermixed with or surrounding cystlike areas of diminished attenuation (see Fig. 5-12).¹⁹¹

Findings on MRI parallel those on CT. Because of the greater inherent sensitivity of MRI for the detection of subacute and chronic hemorrhage and for the demonstration of tumor hypervascularity (curvilinear and racemose signal voids), the overall appearance of the lesion is even more heterogeneous on MRI than on CT.¹⁷⁵ Areas of intratumoral necrosis, which tend to dominate the appearance of the most aggressive of these tumors, appear notably hyperintense on T2-weighted images except where interrupted by more solid masses of cellular debris (Fig. 5-10A). Compared with this central necrotic hyperintensity, the surrounding rim of viable and growing tumor appears significantly less hyperintense (owing to its hypercellularity), with unsharp margins, and may blend with or be indistinguishable from the peritumoral edema.

Virtually all glioblastomas are associated with vasogenic edema in the surrounding peritumoral white matter, usually graded as moderate or severe (Figs. 5-11A and 5-13A).^{5, 191} The origin of this edema is uncertain; it may reflect production of a vascular permeability factor by the tumor cells.¹⁰ Grossly evident mildly hyperdense or hyperintense

Figure 5-10. Glioblastoma multiforme involving the septum pellucidum. *A*, Axial T2-weighted MR image through the inferior aspect of the frontal horns of the lateral ventricles. An ovoid heterogeneously hyperintense mass (arrow) arising from the inferior aspect of the septum pellucidum indents and partially occludes the frontal horns bilaterally. Note the irregularly marginated intratumoral marked hyperintensity suggesting central necrosis. *B*, Following intravenous administration of gadolinium, a coronal T1-weighted image demonstrates intense contrast enhancement (arrow) of the thick peripheral rind with nonenhancement of the central cavity.

Figure 5-11. Left deep frontoparietal glioblastoma with extension through corpus callosum. **A**, Axial T2-weighted MR image through the level of the upper third ventricle. A large area of diffuse hyperintensity involves the left posterior thalamus and basal ganglia and extends posteriorly to involve the subcortical white matter in the left parietooccipital convexity. It is not possible on this image to either define the tumor margins or to separate gross tumor from surrounding edema. The third ventricle and the flow voids of the two parallel internal cerebral veins are bowed to the right of the midline secondary to the left sided deep mass effect. Note that this hyperintensity also extends into and widens the splenium of the corpus callosum (arrow), crossing the midline into the contralateral hemisphere and creating a “butterfly glioma” pattern. **B**, Axial T1-weighted image following intravenous gadolinium demonstrates patchy heterogeneous contrast enhancement within the splenium (arrow) and surrounding the dilated and posteriorly displaced atrium of the left lateral ventricle; the tumor has blocked the posterior portion of the ventricle, and the marginal contrast enhancement of the atrium suggests subependymal tumor spread.

tumor margins are typically unsharp, but they stand out in contrast to the surrounding hypodense or hypointense edematous white matter on CT and on T1-weighted MRI, respectively, after IV administration of a contrast agent.^{38, 51, 95, 111}

Hemorrhage within the tumor is common in these aggressive tumors with extensive angiogenesis. The appearance of hemorrhage in glioblastoma on both CT and MRI differs from that seen in nonneoplastic intracerebral hemorrhage, in that the former is more heterogeneous because of the surrounding and intermixed tumor and necrotic debris (Fig. 5-12).²¹⁵ Also, evolution of intratumoral hemorrhage usually proceeds more slowly compared with hypertensive, posttraumatic, or other nonneoplastic types of parenchymal hematomas.⁹

Contrast enhancement of viable tumor, including the peripheral rim and the intratumoral solid portions, is nearly universal in glioblastomas (Figs. 5-10B, 5-11B, and 5-13B).^{5, 51, 52, 191, 208} The opacifying tumor ring is typically irregular and of varying thickness. The intensity of the enhancement is often significant and correlates with the level of cellular anaplasia,⁵¹ but it does not accurately reflect the extent of microscopic tumor infiltration.^{44, 95} Careful imaging-histopathologic correlation studies have

conclusively established the presence of viable tumor cells well beyond the margin of contrast enhancement, and the zone of apparent edema in the surrounding white matter must be understood as including foci of microscopic tumor infiltration.^{45, 46, 95}

Differentiation by CT or MR among glioblastoma (or other grade IV gliomas), carcinomatous metastasis, and lymphoma is often difficult. All three processes may appear as irregularly rounded, contrast enhancing, ringlike masses with walls of varying thickness. In all, the viable tumor rim is typically irregular and nonuniform in thickness, and histologic examination is usually required for definitive diagnosis. Primary CNS lymphoma is typically more central in location and homogeneously solid (see Fig. 5-45), but central necrosis, infiltration into the corpus callosum and other major white matter pathways, and tumor extension into the meninges and along the ependyma (all common late manifestations in glioblastoma) are not rare occurrences with lymphoma. Occasionally, a large area of active demyelination with inflammation and edema secondary to previously undiagnosed multiple sclerosis may also simulate a glioblastoma on CT or MRI.³⁵

When images demonstrate multiple nodular or ringlike masses, multicentric glioblastoma must be included in the

Figure 5-12. Intratumoral hemorrhage into large right posterior frontoparietal glioblastoma. Axial CT image without intravenous contrast. A large well demarcated hypodense cystic cavity in the deep right frontoparietal white matter is surrounded by poorly defined hypodensity. On the posterior margin of this cavity, there is a sharply defined scythelike hyperdense collection (*arrow*) representing intratumoral hemorrhage. Note the considerable mass effect secondary to diffuse edema in the right frontal lobe with shift of the lateral and third ventricles and the septum pellucidum to the left of the midline. The atrium of the left lateral ventricle is compressed and displaced anteromedially by this cavitated tumor.

differential diagnosis (see Fig. 5-13),^{160, 271} along with metastases and pyogenic cerebral abscesses.²⁶⁸ The peripheral rim of an abscess is typically (but not always) thinner and more uniform than that of a glioblastoma or a metastasis.^{50, 348} MRS has been suggested as a method for differentiating abscess from glioblastoma or metastasis with central necrosis; the chemical shift spectrum in the center of the

lesion reflects high lactate signal in both necrotic tumor and abscess. Sampling of the peripheral rim and adjacent edematous white matter, however, typically demonstrates depressed NAA and elevated choline levels in the case of tumor (Fig. 5-14B), compared with normal choline and NAA levels in the abscess margin.¹³¹ Our experience to date with MR spectroscopy has supported this differentia-

Figure 5-13. Multicentric glioblastoma. Coronal MR images through the posterior atrial region. A, T2-weighted image demonstrates a hyperintense rounded mass in and deep to the high right frontoparietal convexity (*upward pointing white arrow*) and a second similar mass in the inferomedial right temporooccipital cortex and white matter (*downward pointing black arrow*). Between these masses is a large area of greater hyperintensity, likely representing edema with probable microscopic tumor infiltration, which effaces the overlying convexity cortex and severely compresses and obscures the atrium of the right lateral ventricle. B, On a T1-weighted image following intravenous gadolinium administration, both lesions demonstrate inhomogeneous contrast enhancement. The inferomedial tumor has invaded the splenium of the corpus callosum, extending across the midline into the left hemisphere. Note also extension of this tumor inferiorly, protruding into the tentorial notch and impinging on the right side of the superior cerebellar vermis.

Figure 5-14. Glioblastoma with MR spectroscopic correlation. *A*, Axial T1-weighted postgadolinium MR image demonstrates an irregularly margined contrast enhancing left posterior frontal parasagittal tumor involving the white and gray matter of the left cingulate gyrus with associated subfalcine herniation. The square outline overlying the midportion of the enhancing mass indicates the voxel selected for spectroscopic interrogation. *B*, Graphic display of proton spectroscopic interrogation of the tissue included within the voxel outlined on *A* demonstrates markedly reduced concentration of *n*-acetyl aspartate (NAA) (*middle arrow*) with slight elevation of lactate peak (*right arrow*) and marked elevation of choline (*left arrow*). The elevation in lactate reflects tissue necrosis, while the markedly elevated choline peak indicates increased cell membrane turnover. These findings support the diagnosis of a malignant glioma.

tion. However, needle biopsy under imaging guidance remains the most definitive method for establishing the diagnosis and instituting definitive treatment.²²⁰

A commonly encountered clinical problem is the need to differentiate radiation necrosis from recurrent glioblastoma in a patient who has undergone surgical resection and a complete course of radiation therapy and now, several months after the radiation therapy, demonstrates a change in neurologic status. If the followup imaging study demonstrates increases in the size of the apparent tumor mass and the extent of contrast enhancement, differentiation of recurrent tumor from radiation necrosis on the basis of CT or MRI is not possible. In such circumstances, ¹⁸F-FDG PET studies of brain glucose metabolism have shown the level of glucose utilization to be a valid measure of tumor growth,⁸⁹ although one study has challenged these results.²⁷⁶ MRS may be able to provide similar prognostic information (Fig. 5-15), but clinical experience to date is limited.¹⁸³

Gliomatosis Cerebri. A comparatively uncommon pattern of glial neoplasia, gliomatosis cerebri is characterized by widespread diffuse neoplastic infiltration in multiple lobes and both cerebral hemispheres. The extent of infiltration is disproportionate with the other histopathologic features, such as the level of anaplasia and the relative lack of destruction of normal tissues. Despite the extent of tumor infiltration, neural connections are preserved, and

the clinical signs and symptoms are relatively mild. Nevertheless, the clinical course is relentlessly progressive over periods varying from weeks to years.

The process tends to extend along the white matter tracts but also involves the adjacent gray matter with loss of clear gray-white distinction. Grossly, the involved parenchyma is both expanded and distorted by the tumor infiltration. Microscopically, the tumor cells infiltrate between myelinated fibers without destroying them, much like in a low grade astrocytoma, but there is greater cellular atypia and mitotic frequency, and foci of necrosis are occasionally seen.

Diagnostic imaging studies demonstrate the extensive and scattered areas of parenchymal involvement with multiple ill defined areas of hyperintensity on T2-weighted MR images and subtle hypodensity on CT scans (Fig. 5-16A).³⁰⁹ Focal expansion and distortion are seen as areas of diffuse effacement of sulci and compression and displacement of the adjacent ventricles and cisterns. The incidence and level of contrast enhancement are often less than the extent of apparent tumor infiltration (Fig. 5-16B), because enhancement relates closely to the degree of cellular dedifferentiation.¹⁰ Clinically, the principal differential diagnosis is with multiple sclerosis, but the imaging pattern of multiple widespread areas of expansion and distortion as well as the relatively rapid and consistent progressive clinical course favor a diagnosis of neoplasm.

Gliosarcoma. A rare tumor, gliosarcoma consists of

Figure 5-15. Radiation necrosis and recurrent tumor following irradiation of malignant tumor of thalami and brain stem. *A*, Axial T2-weighted MR image demonstrates diffuse hyperintensity of both thalami, likely representing edema (black arrow). There is an ovoid heterogeneously hyperintense mass behind and continuous with the left thalamus with displacement of the internal cerebral veins to the right of the midline. *B*, Axial T2-weighted image at a slightly higher level than *A*. The voxel for MR spectroscopic interrogation is placed in the left posterior thalamic mass. *C*, MR spectroscopic interrogation of the left posterior thalamic region demonstrates depression of the NAA peak (arrow in the center of the graph) with elevation of the choline peak (arrow to the reader's left), indicating the presence of active tumor growth. The other markedly elevated and abnormal peak (arrow located on the reader's right) is lactate, likely representing necrosis of tumor secondary to radiation therapy.

both glial and mesenchymal elements. Most reported patients have been between 50 and 70 years old. The origin of the mesenchymal element remains uncertain and controversial; it presumably arises from spontaneous neoplastic transformation of vascular elements within the glial neoplasm, but prior radiation therapy has been implicated in a few case reports. The mesenchymal element is usually a fibrosarcoma, but other sarcomas have been reported. Immunohistochemistry studies demonstrate both GFAP reactivity, confirming the astrocytic nature of the glial com-

ponent, and positive staining for collagen and reticulin, confirming the mesenchymal component.⁷⁰

The glial component of these mixed tumors is typically glioblastoma, and gross pathology as well as both CT and MRI demonstrate the variegated pattern of that tumor with areas of central necrosis and peripheral infiltration both along white matter tracts and into adjacent gray matter (Fig. 5-17). Invasion into and involvement of the overlying meninges are often noted (Fig. 5-17B); invasion into bone and extracranial soft tissue likely reflects the sarcomatous

Figure 5-16. Gliomatosis cerebri in the left cerebral hemisphere. *A*, On this axial T2-weighted MR image, there is evidence of diffuse enlargement of the left frontal, temporal, and parietal lobes with extensive but ill defined hyperintensity involving the temporoparietal convexity cortex and adjacent white matter (arrows). *B*, Axial T1-weighted image following intravenous gadolinium demonstrates widely separated patchy areas of faint contrast enhancement (arrows), which represent scattered foci of malignant gliomatous infiltration.

Figure 5-17. Gliosarcoma. *A*, Axial CT image following intravenous contrast demonstrates a lobulated mass with variegated contrast enhancement in the high right frontal convexity with multiple intratumoral calcifications (arrow) surrounding an area of central hypodensity that likely represents necrosis. The contrast enhancement crosses the midline into the high left frontal convexity. Extensive white matter hypodensity, likely representing edema, involves the surrounding frontal lobe white matter bilaterally. *B*, Coronal T1-weighted MR image post intravenous gadolinium confirms the presence of a lobulated high right frontal convexity contrast enhancing tumor and also clearly demonstrates the extensive spread of this tumor along the inner table of the skull bilaterally with bandlike meningeal thickening over the convexities of both cerebral hemispheres.

Figure 5-18. Oligodendroglioma. *A*, Axial noncontrast CT image demonstrates a large mass with poorly defined margins in the left midtemporal lobe (*arrow*). The mass is predominantly hypodense, with a large amorphous central calcification, and involves the convexity cortex as well as the underlying white matter. The expanded left temporal lobe herniates across the tentorial margin and compresses the lateral aspect of the left cerebral peduncle. *B*, On this axial T2-weighted image, the large intratemporal tumor appears heterogeneously hyperintense, with the calcified portion (*arrow*) exhibiting lesser intensity. *C*, Axial T1-weighted MR image following intravenous administration of gadolinium. The tumor appears predominantly hypointense, has ill defined margins, and involves mainly white matter but also extends into the convexity cortex and demonstrates faint heterogeneous contrast enhancement (*arrow*).

element within the tumor, and systemic metastasis (a rare occurrence in glioblastoma) is well described for gliosarcoma.^{48, 70, 187}

Oligodendrogliomas

Oligodendrogliomas (tumors derived from oligodendrocytes) represent 15% to 20% of intracranial gliomas and

5% to 10% of all intracranial neoplasms.^{71, 376} The diagnosis is made much more commonly now than in the past, reflecting a reevaluation of the histologic and immunohistochemical criteria that define the distinction between oligodendroglioma and astrocytoma.^{70, 71} These tumors occur principally in the supratentorial white matter. Like low grade astrocytomas, they tend to infiltrate along white matter tracts in a nondestructive manner. However, more

commonly than astrocytomas, oligodendrogliomas may also invade the adjacent cortex, and involvement of deep structures is also common.²⁸⁶ Eighty-five percent occur in the cerebral hemispheres, more than half in the frontal lobes.^{81, 191, 396}

The peak age of incidence of oligodendrogliomas is in the fourth and fifth decades of life; these tumors are much less common in childhood or adolescence.^{70, 273} The initial clinical presentation is most often a seizure.²⁷⁴ Tumor growth is generally slower than in astrocytomas of similar grade, but a more biologically aggressive category is now recognized in the revised WHO classification as anaplastic oligodendroglioma.^{70, 71, 168, 274} Cytogenetic studies have noted loss of the 1p and 19q chromosomes in approximately half of patients with anaplastic oligodendroglioma; on imaging studies, patients with loss of 1p have demonstrated a significant association with positive response to multiagent nitrosourea-based chemotherapy.⁵⁴

Oligodendrogliomas are typically densely cellular and solid, contain multiple irregular masses of dystrophic calcification, and grow very slowly. They can attain considerable size before they produce symptoms.⁷⁰ Areas of cystic degeneration are found in 20% of cases, mainly in the larger tumors.¹⁸⁹ Intratumoral hemorrhage is also a frequent finding.¹⁸⁹

Foci of astrocytoma are frequently found in association with oligodendroglioma, and when these are prominent, the tumor is termed a *mixed glioma*.³⁶⁵ When there is a clear preponderance of neoplastic oligodendrocytes (75% to 90%), the tumor is classified as an oligodendroglioma.³⁰³

On CT, oligodendrogliomas most often appear as masses of heterogeneous density (predominantly hypodense) in the frontal lobe with irregular and poorly defined margins involving the more superficial white matter and frequently infiltrating into the overlying cortex and obscuring the gray-white interface. The characteristic feature in the great majority of cases is the presence of large irregular calcifications, sometimes described as ribbonlike or gyriform in character, within the tumor (Fig. 5-18A).³⁴¹ The frequency of intratumoral calcification in oligodendrogliomas (70% to 90%) is the highest of any cerebral neoplasm,³⁴¹ but overall, intratumoral calcification is most common in astrocytomas (frequency, 25%) because of the much greater prevalence of that lesion.¹⁶⁸ Intratumoral cyst formation is common (20%),¹⁸⁹ but frank intratumoral necrosis is unusual and indicates a poor prognosis.⁴² Contrast enhancement is noted in approximately two thirds of oligodendrogliomas (Fig. 5-18C), but the degree of enhancement is variable and appears to correlate with higher histologic grade and lower survival.^{303, 341}

On MRI, oligodendrogliomas appear heterogeneous on both T1- and T2-weighted spin-echo images because of the presence of intratumoral cysts and calcifications.¹⁴⁵ On T1-weighted images, the tumors appear predominantly hypointense to gray matter, and on T2-weighted images, they are most often hyperintense, with small intratumoral cysts and focal calcifications and hemorrhages contributing to the overall heterogeneity (Fig. 5-18B).^{168, 189} Peritumoral edema is noted in about a third of cases, but erosion of the overlying calvaria may be identified on both CT and MRI when the lesion is peripheral; this finding indicates the

long-standing course commonly associated with oligodendrogliomas.¹⁸⁹

Ependymoma

The ependyma lining the floor of the fourth ventricle is the most common site of origin of intracranial ependymomas (65%). Nevertheless, approximately 30% occur above the tentorium, arising from the walls of the lateral or third ventricles or from ependymal cell rests in the cerebral white matter adjacent to the lateral ventricles.^{226, 286, 303, 315} Infratentorial ependymomas occur predominantly in children between the ages of 1 and 6 years; supratentorial ependymomas occur mainly in the second through the fourth decades of life.^{7, 110, 315}

Posterior fossa ependymomas compose approximately 10% to 15% of all primary CNS neoplasms of childhood and approximately 5% to 10% of all intracranial neoplasms.^{141, 286, 341} They are the fourth most common posterior fossa tumor of childhood,^{18, 22} exceeded only by medulloblastoma, juvenile pilocytic astrocytoma, and brain stem glioma.²²⁸ Ependymomas are usually slow growing tumors of moderate malignancy (WHO grade II), but the prognosis is guarded because of their notable tendency to recur locally and to disseminate via the subarachnoid spaces. The incidence of seed metastases via the CSF is approximately 10% overall but is considerably higher in the infratentorial tumors of early childhood; tumor seeding into the subarachnoid spaces is found initially or on followup studies in approximately a third of fourth ventricle ependymomas.^{101, 226, 286}

Supratentorial ependymomas are commonly paraventricular, located most frequently within cerebral parenchyma near the atrium of the lateral ventricle or the foramen of Monro and presumably arising from ependymal cell rests.²²⁶ Infratentorial ependymomas are lobulated, well circumscribed, exophytic masses that expand within the cavity of the fourth ventricle rather than infiltrate into the surrounding parenchyma. They often extend in a tongue-like fashion through the lateral recesses into the lateral medullary and cerebellopontine angle cisterns (15%) or through the foramen of Magendie into the vallecula (10%).^{18, 226, 286, 303} Tumor growth within the fourth ventricle eventually leads to occlusion of the ventricle with resultant obstructive hydrocephalus.

These tumors are highly cellular, with uniform cells that tend to form characteristic perivascular pseudorosettes.²⁵ Although they do not invade through the ventricular walls, they are firmly attached to the ventricular floor, and complete resection of the tumor base is frequently not possible. The rate of local tumor recurrence after surgical resection is 90% to 95% within 3 years, and the 5 year survival is currently 45% to 70%.^{138, 141, 228, 273, 304} Furthermore, about 25% of ependymomas exhibit features of anaplasia with a high mitotic rate, cellular pleomorphism, and intratumoral necrosis; these are considered WHO grade III.^{25, 70}

Intratumoral calcification and cyst formation are common in ependymomas (20% to 50% of reported cases).^{7, 226, 315, 361} Peritumoral edema is a prominent and frequent finding in association with both cerebellar and cerebral ependymomas.

On noncontrast CT, ependymomas appear as hypodense or isodense, heterogeneous, midline, rounded masses within the fourth ventricle that partially or completely obliterate it.^{200, 226, 303, 315, 361} The tumor is typically well defined by a prominent hypodense halo of peritumoral edema. Aggregates of calcification, usually small and round but sometimes quite large, are found in up to half of these lesions, and focal lucencies resulting from cyst formation are nearly as common.²⁰⁰ In supratentorial tumors, the cysts are both larger and more frequent (up to 80%) than in the

fourth ventricle ependymomas (see Fig. 5–20A).⁷ Intratumoral hemorrhage is relatively less common, with reported frequency of 20% or less.²⁰⁰ After IV administration of contrast agent, the solid portions and cyst walls of the tumor mass exhibit moderate but variable and heterogeneous enhancement.^{7, 110, 200, 315, 361}

The MRI appearance of ependymomas is heterogeneous, reflecting mixed signals from intratumoral calcification, cysts, and hemorrhage. Usually, these tumors are isointense to hypointense relative to white matter on T1-weighted

Figure 5-19. Ependymoma of the fourth ventricle. *A*, Axial T1-weighted image demonstrates a large predominantly hypointense mass filling and distending the fourth ventricle and compressing the pons from behind. Only a small more hypointense crevice at the right lateral margin of the tumor (arrow) indicates the presence of cerebrospinal fluid in the markedly compressed lumen of the fourth ventricle. Small foci of hypointensity within the tumor likely represent areas of calcification. Note the marked dilatation of the temporal horns secondary to obstruction of the fourth ventricle. *B*, On this axial T2-weighted image, the intraventricular tumor appears heterogeneously mildly hyperintense, while the signal within the residual compressed fourth ventricle (arrow) is strongly hyperintense. Intratumoral calcification is strongly hypointense. *C*, Following intravenous administration of gadolinium, an axial T1-weighted image demonstrates irregular heterogeneous intratumoral contrast enhancement (arrow).

images and isointense to hyperintense to white matter on T2-weighted images (Figs. 5-19A, B, and 5-20B).^{110, 200, 311} As on CT, contrast enhancement is the rule for MRI, but it is variable in degree and typically not uniform (Figs. 5-19C and 5-20C). Although the MRI features of ependymoma are nonspecific,^{18, 128, 311} the multiplanar capabilities of this modality offer unique visualization of infratentorial tumor

extent within the cranial vault and the region of the cervico-cranial junction.¹⁰

On both CT and MRI as well as in the clinical setting, the presentation of ependymoma of the fourth ventricle may closely resemble that of medulloblastoma and of JPA. The incidence and extent of intratumoral calcification, heterogeneity of density or signal intensity, and propensity for

Figure 5-20. Supratentorial ependymoma. A, Axial CT image post intravenous contrast demonstrates a cystic appearing hypodense mass with irregular rimlike contrast enhancement (*arrow*) in the medial aspect of the left temporal lobe. B, On this axial T2-weighted MR image, the tumor (*arrow*) exhibits mixed signal intensity; it is predominantly isointense with gray matter and hypointense to cerebrospinal fluid. A tiny ovoid hypointensity in its posteromedial surface likely represents calcification. There is extensive surrounding edema in the temporal lobe and in the lateral aspect of the left cerebral peduncle. C, Axial T1-weighted postgadolinium image demonstrates irregular rimlike and central contrast enhancement (*arrow*) with medial extension into the lateral margin of the midbrain.

tumor extension into the fourth ventricular recesses are greater in ependymomas than in medulloblastomas or astrocytomas. In general, medulloblastomas appear more dense on CT with a lower frequency of intratumoral calcification, and they exhibit more homogeneous contrast enhancement than ependymomas. Definitive differentiation in a given case on the basis of CT or MRI findings may not, however, be possible.²⁰⁰ Astrocytomas tend to occur in slightly older patients and are much less frequently centered in the midline.

Subependymoma

A rare variant of ependymoma that actually consists of both highly differentiated ependymal cells and astrocytes, subependymoma is classified as a benign (WHO grade I) glial neoplasm. It is considered to arise from beneath the ventricular lining and projects into the ventricular cavity as a sharply outlined intraventricular mass but does not extend deeply from its base into the adjacent brain parenchyma (Fig. 5-21). Subependymomas are typically solid and homogeneous, although larger tumors may contain calcifications, microcystic changes, and evidence of intratumoral hemorrhage.¹⁰

Subependymomas occur mainly in the fourth ventricle in older adults; they are often asymptomatic and found incidentally at autopsy.¹⁰ Those that become symptomatic (causing obstructive hydrocephalus) occur mostly in the lateral ventricle in relation to the septum pellucidum and foramen of Monro and much less commonly in the region of the aqueduct.

On CT and MRI, symptomatic lesions in the lateral ventricles usually arise from the septum pellucidum and appear homogeneous in density and signal intensity. On T2-weighted MRI, the tumor appears homogeneously hyperintense to adjacent brain. There is little or no tumoral enhancement after IV administration of contrast medium (Fig. 5-19C). However, larger tumors may exhibit internal heterogeneity of density and signal owing to intratumoral calcification and hemorrhage.^{110, 311}

The differential diagnosis includes central neurocytoma, ependymoma, and subependymal giant cell astrocytoma. Patient age, the nature of the symptoms, the presence of associated disease, tumor size, the presence and extent of calcification, cystic change, evidence of hemorrhage, and contrast enhancement are the key factors in making the differentiation.

Choroid Plexus Papilloma and Carcinoma

Papillomas arising in the choroid plexus are benign intraventricular neoplasms that locally expand the involved ventricle and cause hydrocephalus, which may be secondary to ventricular obstruction, overproduction of CSF, or impairment of CSF absorption. Choroid plexus papillomas represent less than 1% of all brain tumors but are more common in young children (3% of all pediatric brain tumors), particularly in the neonatal period; 85% occur in the first 5 years of life, and these tumors represent 40% of all brain tumors in the first 60 days of life.^{200, 270, 303}

The atria of the lateral ventricles and the fourth ventricle are the most common sites of involvement. An age disparity exists with regard to tumor location, the lateral ventricle tumors occurring mainly in young children and the fourth ventricle papillomas appearing more commonly in adults.^{11, 286} It is not uncommon for the fourth ventricle tumors to extend through the lateral recesses and protrude into the cerebello-pontine angle cisterns.²⁵³

Histologically, choroid plexus papillomas consist of well differentiated proliferation of both the surface epithelium of the choroid plexus and the underlying vascular connective tissue core and are usually classified as WHO grade I.^{70, 286} They grow slowly and are noninvasive, tending to expand within the confines of the ventricle or its outlet foramina.^{70, 253, 303} Occasionally, however, the epithelium may exhibit malignant change, and in such cases, the tumors are classified as carcinomas; they may extend into the adjacent brain parenchyma.²²¹ The prognosis in these malignant choroid plexus tumors depends on the completeness of surgical resection, but overall, the 5 year survival ranges from 26% to 40%.²⁵⁴

Because of the friability and high vascularity of choroid plexus papillomas, intratumoral and intraventricular hemorrhage are common.^{70, 201, 304}

On CT, choroid plexus papillomas appear as large, rounded or lobulated, isodense or hyperdense intraventricular masses that engulf and separate the normal choroid plexus calcifications and exhibit intense homogeneous contrast enhancement.^{166, 221, 370} Small hypodense, non-enhancing foci are occasionally identified within these tumors.^{166, 370}

On MRI, choroid plexus papillomas are usually isointense or hypointense with respect to brain on T1-weighted images and heterogeneously hyperintense relative to brain on T2-weighted images (Fig. 5-22A, B);^{65, 200} the heterogeneity of signal intensity within the tumor mass may be due to areas of vascularity, calcification, or previous hemorrhage (Fig. 5-22A). As noted previously, the tumor typically expands the ventricle locally at the site of origin and may obstruct ventricular drainage, causing dilatation (entrapment) of the more proximal portion of the affected ventricle.¹¹ On both CT and MRI, these tumors usually demonstrate intense contrast enhancement (Fig. 5-22C), which may be homogeneous or heterogeneous, depending on the tumor contents.

The differential diagnosis of choroid plexus papilloma on imaging studies usually includes ependymoma in older children and adults and meningioma in adults. The lobulated tumor margins, the lack of invasion of brain parenchyma despite the large tumor size, and the heterogeneous signal pattern within the tumor all aid in distinguishing this lesion.

Nonglial Tumors

Neuronal and Mixed Neuronal and Glial Tumors

In this group of tumors of neuroepithelial origin, neuronal and glial differentiation are present in varying degrees. The 1993 revised WHO classification of tumors of the CNS includes the following recognized entities:

Figure 5-21. Subependymoma of the fourth ventricle and vestibular schwannoma in the right cerebellopontine angle. Axial T1-weighted (A) and T2-weighted (B) MR images demonstrate a small sharply marginated isointense (T1-weighted)/hyperintense (T2-weighted) nodular intraventricular mass in the central and left lateral aspects of the fourth ventricle (white arrows). The mass appears continuous with the left lateral wall of the ventricle. Also evident is a rounded heterogeneously hypointense (T1-weighted)/hyperintense (T2-weighted) mass in the right cerebellopontine angle and internal auditory canal that indents the lateral aspect of the pons and middle cerebellar peduncle and the anterior margin of the right cerebellar hemisphere (black arrows). C, Axial T1-weighted image post intravenous gadolinium administration demonstrates nearly homogeneous contrast enhancement of both lesions; the uptake of contrast in the intraventricular nodule is more subtle than in the cerebellopontine angle lesion.

ganglioglioma, gangliocytoma, dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease), desmoplastic infantile ganglioglioma, dysembryoplastic neuroepithelial tumor, and central neurocytoma.^{163, 303}

Ganglioglioma and Gangliocytoma

Gangliogliomas are uncommon low grade tumors consisting of a mixture of neoplastic astrocytes and dysplastic

neurons. Slow growing neoplasms with well differentiated ganglion cells and a low grade astrocytomatous stroma,²⁸⁶ these tumors are considered WHO grade I or II.^{70, 168} Gangliocytomas (also known as ganglioneuromas) are relatively less common and contain only neuronal elements; they are classified as WHO grade I.²⁰⁰ Together, these tumors account for 1.3% of all primary brain tumors.¹⁶⁸

Gangliogliomas and gangliocytomas occur in young

Figure 5-22. Choroid plexus papilloma of the left lateral ventricle. *A*, Axial T1-weighted MR image demonstrates an intraventricular mass with heterogeneous signal intensity in the body of the left lateral ventricle (arrow). The lateral portion of this mass is hyperintense (likely indicating the presence of subacute hemorrhage), while the medial portion is mainly hypointense relative to the white matter. *B*, On this axial T2-weighted image, the tumor (arrow) appears slightly hyperintense to adjacent brain but hypointense to the fluid in the lateral ventricles. *C*, Axial T1-weighted postgadolinium image demonstrates heterogeneous contrast enhancement of the tumor mass (arrow).

people (peak incidence in the second decade of life) and constitute approximately 3% to 4% of primary brain tumors in children.^{155, 226} They are found most commonly in the temporal lobes but may occur anywhere in the cerebral hemispheres.^{229, 363} The clinical presentation is usually with seizures of long duration, and gangliogliomas are considered the most common cause of chronic temporal lobe epilepsy.²²⁹ These tumors are usually well circumscribed

solid masses but may include one or more cysts.^{59, 70} Gross total resection of a tumor is the treatment of choice. Overall, gangliogliomas and gangliocytomas have a 92% 3 year survival.¹⁵⁵ In approximately 10% of cases, however, the tumor is more aggressive; in these cases, the malignant element is always glial.⁷⁰

Diagnostic imaging findings are relatively nonspecific and are similar to those in other low grade intracerebral

neoplasms.^{168, 200} Noncontrast CT scans demonstrate relatively well circumscribed hypodense (occasionally isodense with adjacent brain) lesions typically located in the periphery of the hemisphere with little associated mass effect or surrounding vasogenic edema. Foci of calcification are identified in a third to 40% of cases and cysts in half of cases.^{155, 226, 363, 371} Calcification is less common in the noncystic tumors.¹⁶⁸ Rarely, a peripherally located indolent tumor may erode the inner table of the overlying skull.²²⁶ Hemorrhage is rare in these tumors.²²⁶ Contrast enhancement is observed in about 50% of cases and may be homogeneous or heterogeneous, depending on the presence and size of cystic and calcific changes.^{59, 155, 363}

On MRI, these tumors (like many other intracerebral neoplasms) are usually heterogeneous in appearance, predominantly hypointense to gray matter on T1-weighted images and hyperintense on T2-weighted images (Fig. 5-23A).^{59, 155, 323, 364, 368} Mild to moderate contrast enhancement of the solid noncystic portion of the tumor is found in the majority of cases on both CT and MRI (Fig. 5-23B).⁵⁹

The findings on CT and MRI in these ganglion cell tumors are not characteristic; oligodendroglioma is a common differential consideration. However, in a young patient with a protracted history of seizures and a relatively well circumscribed cystic tumor containing calcification in the periphery of the temporal lobe with little or no associated mass effect, ganglioglioma should be strongly considered.^{59, 155, 275, 314, 363}

Dysplastic Gangliocytoma of the Cerebellum

A rare lesion, dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease) is considered a complex hamartoma or malformation and is classified as WHO grade I.³⁵⁰ Dysplastic gangliocytoma may exist as an isolated entity or as part of Cowden's disease, a rare syndrome with multiple mucosal hamartomas.^{178, 350} The clinical presentation is usually ataxia and signs of increased intracranial pressure in a young adult. A large dysplastic mass occupies most or all of the cerebellar hemisphere with thickening of the granular and molecular layers of the overlying cerebellar cortex (Fig. 5-24A). The enlarged mass causes displacement and compression of the fourth ventricle. On MRI, the mass is poorly demarcated, hypointense on T1-weighted images and hyperintense on T2-weighted images, and the thickened folia present a distorted striate pattern (Fig. 5-24B).³⁰⁷ Contrast enhancement of either the tumor or the thickened cerebellar folia is unusual (Fig. 5-24C).¹⁷⁷

Desmoplastic Infantile Ganglioglioma

Desmoplastic infantile ganglioglioma (DIG) is an unusual lesion that occurs in young infants. It consists of immature neurons and astrocytes together with extensive fibrocollagenous (desmoplastic) thickening and cyst formation. The solid desmoplastic portion is often located adja-

Figure 5-23. Ganglioglioma of the right temporal lobe. *A*, Axial T2-weighted MR image demonstrates a well circumscribed cystic mass (arrow) with a hypointense rim (secondary to calcification) in the region of the right parahippocampal gyrus and surrounding hyperintensity (due to edema). There is associated mass effect with effacement of the sulci of the right temporooccipital convexity, but there is no evidence of tentorial herniation. *B*, On this postgadolinium T1-weighted coronal image, peripheral rimlike contrast enhancement (arrow) outlines the margins of this cystic tumor, which is located immediately above the right leaf of the tentorium. The contents of the cyst are slightly hyperintense relative to cerebrospinal fluid, reflecting a higher protein content.

Figure 5-24. Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos). *A*, Axial CT image without intravenous contrast demonstrates a poorly marginated heterogeneous predominantly hypodense mass (*arrow*) occupying most of the right cerebellar hemisphere and displacing the fourth ventricle to the right of the midline. A striate pattern of calcification is noted within this process. *B*, On this T1-weighted axial noncontrast MR image, the poorly marginated hypointense mass presents a distorted internal architecture (*arrow*) and compresses and displaces the pons anteriorly and to the left. *C*, Axial T1-weighted image post intravenous gadolinium: there is no evident contrast enhancement of this hamartomatous process (*arrow*).

cent to the meninges. Despite its variegated appearance, this tumor is classified as WHO grade I and has a favorable long term prognosis after complete excision.¹⁵⁵

DIGs are large and superficial hemispheric tumors that occur mainly in the frontal and parietal lobes and present a markedly heterogeneous appearance on both gross inspection and MRI (Fig. 5-25).^{155, 209, 326} The solid portions of this tumor are hypointense relative to normal brain on

T2-weighted images and frequently demonstrate intense contrast enhancement.^{155, 326} DIG differs from the usual ganglioglioma in that it presents in infancy, is predominantly frontoparietal in location, and has dense desmoplasia.²⁰⁰ On MRI, the intermixed collagenous and multicystic pattern of this lesion most resembles that of a primitive neuroectodermal tumor (PNET), which carries a much less favorable prognosis; however, PNET is also

Figure 5-25. Desmoplastic infantile ganglioglioma (DIG). A, Axial T2-weighted MR image demonstrates a well circumscribed heterogeneous left high frontal convexity tumor that is predominantly hypointense to adjacent brain (arrow). On its posteromedial aspect, there are two small cysts and one large ovoid cyst on the left and a single large cyst on the right, all with hyperintense contents. There is extensive white matter edema bilaterally, surrounding the large cysts and extending into the left frontoparietal convexity gyri. Following intravenous administration of gadolinium, axial (B) and left parasagittal (C) T1-weighted images demonstrate intense contrast enhancement of the superficial solid area of this tumor (arrows), which consists of thick dense fibrocollagenous (desmoplastic) tissue. Contrast enhancement is also seen to a variable degree in the rims of the cystic elements of this lesion. On C, note the posteroinferior displacement and compression of the atrium and temporal horn of the left lateral ventricle by the large left cystic mass.

characterized by the common presence of intratumoral calcification, hemorrhage, and necrosis, findings that are uncommon in DIG.²⁰⁰

Dysembryoplastic Neuroepithelial Tumor

Dysembryoplastic neuroepithelial tumors (DNETs) are uncommon benign intracortical tumors that characteristically occur in young patients (<20 years) above the tentorium, mainly in the temporal lobe (60% to 80%) or frontal lobe.^{79, 80, 168, 169, 303} They can be multifocal and rarely arise in the deep cortical structures. The patients typically present with intractable partial seizures. Partial or complete

excision is the treatment of choice, and no recurrences have been reported.⁸⁰ The tumor is termed “dysembryoplastic” because of its multinodularity, with areas of cortical dysplasia at the margins between the tumor nodules and the adjacent brain.^{79, 80}

DNETs are lesions of long standing that most frequently involve the convexity cortex and often protrude beyond the adjacent cortical margin, eroding the overlying inner table of the calvarium.^{168, 169, 303} The imaging findings, except for the superficial cortical location, are similar to those of other low grade glial tumors (astrocytoma, oligodendroglioma). On CT, DNET typically appears as a well circumscribed hypodense superficial mass, occasionally with intratumoral

calcification, or cystic change, or both.^{168, 242, 303} MRI demonstrates a mass centered in the convexity cortex and bulging externally that is hypointense to adjacent brain on T1-weighted images (Fig. 5-26B) and hyperintense on T2-weighted images (Fig. 5-26A) with no surrounding edema.^{168, 169, 303} The protruding external margin may present a "soap bubble" appearance, reflecting internal cystic change.¹⁷⁸ Contrast enhancement is seen in only a minority of these lesions (Fig. 5-26C).^{169, 178, 242}

Central Neurocytoma

A relatively rare, benign, slow growing (WHO grade II) intraventricular tumor, central neurocytoma has now been recognized as a separate entity.^{70, 303} It occurs almost exclusively in the anterior portion of the lateral ventricle, arising from the superolateral ventricular wall and extending medially adjacent to the septum pellucidum and the foramen of Monro; extension through the foramen into the third ventricle is unusual. No such tumors have been

Figure 5-26. Dysembryoplastic neuroepithelial tumor (DNET). A, Axial T2-weighted MR image demonstrates a well circumscribed superficial cystic mass (arrow) in the right posterior frontal convexity cortex with an outwardly bulging external surface. T1-weighted images post intravenous gadolinium in the axial (B) and coronal (C) planes demonstrate a thin rim of contrast enhancement surrounding the cyst (arrows) which is centered in the right posterior frontal convexity cortex and is eroding the inner table of the overlying bony calvarium.

reported arising in the third or fourth ventricles, and only a few hemispheric lesions have been found.²⁴¹ Central neurocytomas are tumors of young adults and are rare in children and the elderly. Patients typically present clinically with headache and signs of increased intracranial pressure secondary to ventricular obstruction.^{70, 241} Partial or complete surgical excision is the treatment of choice, and no deaths from tumor growth or recurrence have been reported.³⁵⁶

Histologically, central neurocytoma is identical to oligodendroglioma. It is characterized by nests of small well differentiated cells separated by thin fibrovascular septa.^{10, 356} Intratumoral calcification and multiple small cysts are common findings, but hemorrhage (either intratumoral or intraventricular) is unusual. It is only with electron microscopy and immunohistochemistry that its neuronal origin can be determined.⁷⁰

CT scans demonstrate a sharply margined, inhomogeneous, isodense to slightly hyperdense intraventricular mass with a broad-based attachment to the wall of the frontal horn or anterior body of the lateral ventricle and abutting the septum pellucidum. Calcifications, either coarse or globular, and multiple small intratumoral hypodense cysts are found in 50% or more of central neurocytomas. Mild to moderate contrast enhancement of the isodense to hyperdense regions is common.^{33, 119, 356}

The findings on MRI are similar. The tumor demon-

strates a heterogeneous pattern with intermixed foci of isointensity (compared with adjacent gray matter) and hypointensity (due to calcifications and cysts) on T1-weighted images and isointensity to hyperintensity on T2-weighted images (Fig. 5-27A). Inhomogeneous mild contrast enhancement is common (Fig. 5-27B).^{33, 119, 356}

The differential diagnosis is that of a well circumscribed intraventricular mass at or near the foramen of Monro and includes ependymoma and subependymoma. The absence of both deep extension into adjacent brain parenchyma and intratumoral hemorrhage as well as the relatively young age of the patient favors the diagnosis of central neurocytoma.^{10, 241}

Pineal Parenchymal Tumors

Tumors arising within the parenchyma of the pineal gland constitute less than 1% of all primary brain tumors in adults.⁷⁰ However, pineal tumors represent nearly 10% of all pediatric brain tumors.²⁰⁰ The most common tumors to involve the pineal gland are the germ cell tumors, which constitute 50% to 70% of pineal region tumors and are discussed elsewhere in this chapter.

Pineal parenchymal tumors represent only 15% to 30% of pineal region neoplasms.^{305, 360} They include a range from primitive undifferentiated (pineoblastoma) through

Figure 5-27. Central neurocytoma in the anterior body and frontal horn of the left lateral ventricle. A, Axial T2-weighted MR image demonstrates a large multilobulated heterogeneous but predominantly isointense (with gray matter) intraventricular mass arising from the lateral wall of the left lateral ventricle (arrow) with multiple small hyperintense foci and one large intratumoral hyperintense cyst. The tumor expands the left lateral ventricle. Enlargement of both lateral ventricles is likely secondary to obstruction of the foramen of Monro by this mass. B, Coronal T1-weighted spoiled gradient echo image following intravenous gadolinium: the plane of section passes through the anterior portion of the tumor. The more solid portion of this tumor demonstrates faint contrast enhancement. Note the extension of the tumor inferiorly and medially at a level just anterior to the foramen of Monro.

transitional forms to moderately mature and well differentiated (pineocytoma).^{200, 292}

Pineoblastoma

Pineoblastomas are pediatric tumors with a peak incidence in the first two decades of life and rarity after age 30. These malignant, highly cellular, undifferentiated small cell tumors are histologically and histochemically identical

with other primitive neuroectodermal tumors and exhibit similar biologic behavior. They are locally invasive and may spread into the third ventricle, the thalami, and the quadrigeminal plate. Pineoblastomas frequently contain areas of hemorrhage and necrosis, and intratumoral calcification is common.^{10, 292} Presenting symptoms include precocious puberty (possibly related to destruction of normal pineal tissue with loss of melatonin secretion),²⁵ Parinaud's syndrome and other cranial nerve deficits, and obstructive

Figure 5-28. Pineoblastoma. Axial T2-weighted MR image (A) demonstrates a small ovoid tumor mass (arrow) arising in the region of the pineal gland and protruding posteriorly into the quadrigeminal plate cistern. The tumor is heterogeneous in signal but predominantly hyperintense to gray matter. Axial T1-weighted pre (B) and post (C) intravenous gadolinium images demonstrate intense homogeneous contrast enhancement of the entire tumor mass (arrows). Note the blunting of the posterior margin of the third ventricle by this pineal tumor.

hydrocephalus. Dissemination via the CSF with leptomeningeal and ependymal metastases occurs in 10% of cases and may be found at the time of initial diagnosis. The 5-year survival rate is 58%.²⁹²

On CT, pineoblastomas appear hyperdense with irregular intratumoral calcification, infiltration into neighboring structures, and mass effect upon the posterior aspect of the third ventricle and the tectum of the midbrain. They demonstrate dense contrast enhancement. On MRI, pineoblastomas appear heterogeneous in signal, predominantly hypointense to gray matter on T1-weighted images and isointense with gray matter on T2-weighted images, with interspersed foci of hypointensity secondary to intratumoral necrosis and calcification (Fig. 5-28A, B).^{10, 305, 332, 360} As on CT, contrast enhancement of the solid portion of the tumor is the rule (Fig. 5-28C). The chief differential consideration is germinoma, which may look identical on CT and MRI.

A rare occurrence that is nevertheless important for recognition and management is the association of bilateral retinoblastomas with pineoblastoma, often termed *trilateral retinoblastoma*. This condition, an inherited disorder occurring in very young children (<2 years), is found in 3% of patients with bilateral retinoblastomas.²⁶⁹

Pineocytoma

Pineocytomas are tumors of adults with a mean age of presentation of 36 years. Compared with pineoblastomas, these lesions are less densely cellular with well differentiated

cells that have more cytoplasm arranged in lobules in an architecture similar to that of the normal pineal gland.^{25, 292} They tend to follow a slower and more benign clinical course, but transitional tumors intermediate in cellularity and mitotic activity also exist.^{70, 292} Intratumoral calcification is present in more than 50%. Subarachnoid seeding is not seen in the more benign neoplasms. The 5 year survival for pineocytomas is 67%.²⁹²

On CT, the typical appearance is of a rounded, well circumscribed, homogeneously hyperdense, lobulated expansile mass with intratumoral calcification situated at and often obstructing the posterior margin of the third ventricle (Fig. 5-29A).^{200, 269} There is no evidence of invasion of neighboring structures. Multiplanar MRI demonstrates a rounded or ovoid mass compressing the posterior margin of the third ventricle and the superior aspect of the quadrigeminal plate. The mass is homogeneously hypointense to isointense on T1-weighted images and hyperintense relative to gray matter on T2-weighted images.^{200, 305, 332, 360} The signal characteristics reflect the higher water content of these more mature tumors compared with pineoblastomas.¹⁰ Contrast enhancement of all or a major portion of a pineocytoma is the rule on both CT (Fig. 5-29B) and MRI.

Embryonal Tumors

The terminology regarding primitive or embryonal tumors of neuroepithelial origin has been a source of controversy for nearly two decades. Gradually, however, a con-

Figure 5-29. Pineocytoma. Axial noncontrast (A) and postcontrast (B) CT images demonstrate a well circumscribed markedly hyperdense mass in the midline (arrow in A) in the pineal region with bilateral lobulated intense contrast enhancement impinging on the medial aspects of both thalami (arrow in B). The tumor is partially obstructing the posterior aspect of the third ventricle, accounting for the enlarged lateral and anterior third ventricles.

sensus appears to be emerging concomitant with advances in applied molecular biology.²⁵ Primitive neuroectodermal tumors (PNETs) of the CNS appear to be one group of a larger category of embryonal tumors that occur throughout the body (e.g., neuroblastomas of the adrenal and sympathetic ganglia).^{25, 281} These are the second most common intracranial tumors of childhood, representing approximately 15% to 20% of all childhood brain tumors and exceeded in frequency only by the astrocytomas.²⁵ They have a common histology, consisting of densely packed undifferentiated round cells with a high nuclear-to-cytoplasmic ratio and high mitotic activity but follow divergent patterns of differentiation.²⁸¹

The classic PNET is the medulloblastoma of the cerebellar vermis, which constitutes 85% of this group of tumors.²⁵ The remaining 15%, almost all supratentorial, include pineoblastomas (see earlier), ependymoblastomas, and medulloepitheliomas. The histogenesis of PNETs is undetermined, but one hypothesis is that they arise from immature pluripotential precursor cells in the subependymal layers of the developing ventricular system and in the external granular layer of the cerebellum.^{25, 281}

Medulloblastoma

An invasive and highly malignant tumor (WHO grade IV), medulloblastoma is the second most common primary brain tumor of childhood and the most common pediatric posterior fossa neoplasm.^{115, 168} Although medulloblastomas may occur at any age, 75% present clinically before age 15 years. There are two distinct age peaks, at 4 to 8 years and 15 to 35 years.¹⁶⁸ In children, medulloblastomas are primarily tumors of the cerebellar vermis (Fig. 5-30), but in adults, they tend to be located more laterally in the cerebellar hemispheres (Fig. 5-30).^{48, 167, 281, 286, 372} The typical clinical presentation consists of signs of obstructive hydrocephalus, cerebellar dysfunction, or both—headache, nausea, vomiting, and ataxia.¹⁶⁸

These aggressive tumors grow rapidly, with extension from the vermis into the fourth ventricle, and spread inferiorly into its recesses and outlet foramina and superiorly into the aqueduct.^{303, 335} More than 90% present clinically with hydrocephalus.²⁰⁰ They have a strong tendency to seed via the CSF, and approximately 40% demonstrate subarachnoid or retrograde ependymal metastases at the time of initial diagnosis.^{96, 176} They are highly radiosensitive, and the standard treatment approach is gross total resection plus chemotherapy and total craniospinal axis irradiation.¹⁷⁶ Ten year survival rates are in the range of 50% to 70%, but the prognosis is poorer in children younger than 3 years.^{34, 92, 200} Recurrence after the initial treatment regimen is about equally distributed between local regrowth at the primary tumor site and distant metastasis.³⁴ Systemic metastasis, a highly unusual occurrence with most CNS primary neoplasms, is identified in approximately 5% of patients, mainly to bone.¹⁶⁸

Compared with other highly aggressive brain tumors, medulloblastomas appear relatively discrete and solid with convex margins on gross inspection but may contain foci of necrosis and hemorrhage.^{25, 200} Microscopically, the tumor cells tend to be arranged in pseudorosettes, and areas of vascular proliferation, cellular pleomorphism, and calci-

fication are occasionally identified. Electron microscopy and immunostaining usually confirm neuronal differentiation.²⁵ Approximately 15% of medulloblastomas contain a significant amount of collagen and reticulin and may demonstrate a nodular pattern; designated desmoplastic medulloblastomas, these tumors are relatively more common in the cerebellar hemispheres in adolescents and young adults.^{25, 193}

On noncontrast CT scans, medulloblastomas appear as rounded or oblong, mainly homogeneous, isodense to slightly hyperdense masses centrally located in the inferior vermis and cavity of the fourth ventricle (Fig. 5-30A).^{19, 226, 320, 372} Differentiation of medulloblastoma from diffuse solid cerebellar astrocytoma is most reliably made on noncontrast CT.³⁷² The solid hyperdense appearance of medulloblastoma reflects the dense cellular nature of this tumor, whereas astrocytomas are typically rather uniformly hypodense.^{109, 112} Obstruction of the fourth ventricle, inferior aqueduct, or both with resulting enlargement of the third and lateral ventricles is commonly seen on CT at the time of clinical presentation. Punctate or nodular intratumoral calcifications are identified in 10% to 20% of cases.^{167, 168, 335, 362} Hypodense intratumoral foci of necrosis and cysts are found in up to 50% of medulloblastomas (see Fig. 5-30A).^{226, 320, 362} Many medulloblastomas are surrounded by a thick, poorly marginated, hypodense halo representing extensive peritumoral edema. The imaging findings in young adults are similar, except for the more lateral (hemispheric) location of the tumor.³⁷²

After IV administration of contrast medium, moderate to intense homogeneous enhancement of the solid tumor mass is the rule in medulloblastomas,^{19, 167, 335, 372} although approximately 10% do not demonstrate contrast enhancement on CT.²²⁶ Areas of tumor seeding in the posterior fossa cisterns or in the third or lateral ventricles exhibit similar homogeneous contrast enhancement in a nodular or sheetlike configuration.^{320, 372}

The appearance of medulloblastomas is less specific on MRI than on CT. The tumors are mildly hypointense to isointense relative to the adjacent cerebellar vermis on T1-weighted images and isointense to slightly hyperintense on T2-weighted images (Figs. 5-30B, C and 5-31A). Isointensity (or even hypointensity) of the tumor matrix on T2-weighted images are likely due to the hypercellularity and high nuclear-to-cytoplasmic ratio of this tumor.^{22, 83, 128, 197} However, heterogeneity of signal intensity is often seen on the T2-weighted images (Figs. 5-30C and 5-31B) secondary to intratumoral cysts, necrosis, vascular flow voids, and hemorrhage.^{168, 200, 335} Contrast enhancement of the solid portions of the tumor, seen in more than 90% of patients, is typically intense and homogeneous (Fig. 5-31B) but may be irregular and patchy (Fig. 5-30D).^{168, 173, 278, 335} MRI with gadolinium enhancement is very sensitive for the detection of tumor spread and metastatic seeding in the cranial and spinal subarachnoid spaces.^{173, 278, 303, 335}

Supratentorial Primitive Neuroectodermal Tumor

Fifteen percent of all PNETs of the CNS occur above the tentorium.²⁵ However, they represent less than 1% of all pediatric brain tumors. Like their infratentorial counter-

Figure 5-30. Medulloblastoma of the cerebellar vermis in an 11-year-old child. *A*, Axial noncontrast CT image demonstrates a large lobulated hyperdense round tumor (*arrow*) with an internal hypodense cavity to the right of the midline that compresses the fourth ventricle from behind. An ill defined faintly hypodense band surrounding the hyperdense mass represents white matter edema. The intratumoral area of marked hypodensity to the right of the midline likely represents necrosis. A smaller focus of lesser hypodensity on the left posterolateral tumor margin suggests an intratumoral cyst. These findings are confirmed on noncontrast axial T1-weighted (*B*) and T2-weighted (*C*) MR images; the solid portion of the tumor appears mildly hypointense on T1-weighting and mildly hyperintense on T2-weighting (*arrows*). Following intravenous gadolinium, an axial T1-weighted image (*D*) demonstrates irregular patchy contrast enhancement of the solid areas of the tumor (*arrow*).

Figure 5-31. Medulloblastoma of the anteroinferior right cerebellar hemisphere in a 26-year-old patient. *A*, Axial T2-weighted MR image demonstrates a poorly circumscribed mass with a heterogeneous signal pattern in the anteroinferior portion of the right cerebellar hemisphere. Irregular areas of pronounced hyperintensity (arrow) are interspersed in a mildly hyperintense background that likely represents surrounding edema. The tumor extends medially into the inferior vermis. *B*, After intravenous administration of gadolinium, the tumor demonstrates homogeneous contrast enhancement with well circumscribed margins (arrow). Punctate intratumoral hypointensities represent enlarged vascular channels and/or focal calcifications.

parts, they occur mainly in the very young (65% of patients <5 years, 85% <10 years).⁶² Patients may present clinically with seizures or with symptoms and signs of increased intracranial pressure. The distribution of these aggressive tumors within the cerebral hemispheres is, in diminishing order of frequency, frontal, parietal, temporal, and occipital.²⁰⁰ Approximately one third are pineoblastomas; the remainder are central neuroblastomas,^{62, 83} ependymoblastomas,⁹² ganglioneuroblastomas, medulloepitheliomas, and other rare immature round cell tumors.²⁸¹

On CT scans, supratentorial PNETs appear heterogeneous and well circumscribed. The heterogeneity reflects cystic or necrotic changes and intratumoral hemorrhage.²⁰¹ The solid elements are hyperdense because of their high cellularity and demonstrate contrast enhancement. Coarse calcifications are described in 50% to 70%, a much higher proportion than in cerebellar medulloblastomas.^{200, 281} Supratentorial PNETs share with their infratentorial counterparts a strong propensity for spread via CSF.⁸³

MRI also demonstrates heterogeneity of signal intensity on both T1-weighted and T2-weighted images (Fig. 5-32). They are often large tumors with relatively lesser degrees of surrounding edema.^{83, 92} The differential diagnosis includes other large well circumscribed supratentorial tumors, such as ependymomas and oligodendrogliomas.²⁰⁰ As on CT, the solid portions of the tumor demonstrate strong contrast enhancement, a feature that may aid in the differentiation.

Tumors of the Cranial Nerves

Approximately one third of all intracranial masses are nonglial primary neoplasms of the CNS, almost all of which are extraaxial in origin and location.³⁰² The most common of these are schwannomas of the cranial nerves and meningiomas.

Within the brain and spinal cord, the nerve fiber tracts are surrounded by oligodendrocytes. However, as the cranial nerves emerge from the brain, there is a transition zone beyond which the oligodendrocytes do not extend but are instead replaced by Schwann cells (also called neurilemmal cells), which surround and ensheath the extraaxial portions of the cranial nerves, the spinal nerve roots and nerves, and the peripheral nerves. Within the cranial vault, tumors arising from these nerves nearly all represent schwannomas.

The other major primary tumor of the cranial nerves is neurofibroma. Neurofibromas differ from schwannomas not only in site of origin but also in histology and natural history.^{48, 354} Malignant degeneration is essentially unknown in schwannomas, but both malignant degeneration of neurofibromas and primary malignant peripheral nerve sheath tumors are recognized but uncommon occurrences.^{339, 354}

Schwannoma

Schwannoma is a benign (WHO grade I) encapsulated tumor that arises from the Schwann cells of the nerve

Figure 5-32. Primitive neuroectodermal tumor in the left parietooccipital region (postcraniotomy). *A*, Axial T2-weighted MR image demonstrates an ovoid heterogeneously hyperintense mass in the left parietooccipital white matter with extension into the overlying convexity cortex and a single large intratumoral sharply margined central collection of marked hyperintensity, likely representing a combination of necrosis, surgical resection cavity, and/or cyst formation (arrow). The mass compresses and displaces the atrium of the left lateral ventricle from behind. *B*, Following intravenous gadolinium, an axial T1-weighted image demonstrates irregular contrast enhancement within the tumor interstices without enhancement of the central cavity (arrow).

sheaths of cranial and spinal nerves.³⁵⁴ It is estimated to account for between 5% and 10% of primary intracranial neoplasms and for nearly 30% of intraspinal tumors.^{57, 302}

Intracranial schwannomas occur in all age groups, but the peak incidence is in the fourth through the seventh decades of life.^{57, 302, 354} There is a distinct sex predilection with a female-to-male ratio of 2:1, although no such predilection exists in regard to spinal schwannomas.^{57, 302}

By far the most common site of intracranial involvement is the superior vestibular division of the eighth cranial nerve.^{207, 302} Trigeminal nerve schwannomas are much less common, with facial, trochlear, and abducens nerve tumors only rarely reported.²⁴¹ Only the first (olfactory) and second (optic) cranial nerves lack Schwann cell sheaths and are therefore not potential sites of origin. The clinical presentation varies according to the site of origin. Vestibular schwannoma (also called acoustic neuroma or neurinoma) typically presents with symptoms of a mass in the cerebellopontine angle, including tinnitus, sensorineural hearing loss, and facial paresthesias.^{241, 302, 354} Despite the tumor's origin from the vestibular nerve, symptoms and signs of vestibular dysfunction do not become manifest until relatively late. These tumors have a distinct propensity to involve the sensory nerve roots, and motor symptoms are uncommon.³⁵⁴

Multiplicity of intracranial schwannomas strongly suggests the presence of neurofibromatosis 2 (NF2), a congenital inherited disorder associated with a mutation on the

long arm of chromosome 22.²²³ The occurrence of bilateral acoustic schwannomas (see Fig. 5-34) is pathognomonic of this disorder, which has also been termed MISME (multiple inherited schwannomas, meningiomas, and ependymomas).³⁰⁴ In fact, labeling this disorder neurofibromatosis is a misnomer, because neurofibromas are not a part of its constellation of abnormalities. Patients with this disorder typically present clinically in the second and third decades of life, much earlier than those with the sporadic intracranial schwannoma.³⁰²

On gross inspection, schwannomas appear as focal, well circumscribed, globular or ovoid masses that do not infiltrate the nerve but rather arise and grow eccentrically, displacing the uninvolved portion of the cranial nerve of origin to the side.^{48, 241, 302} As the tumor grows and matures, it may undergo cystic degeneration or develop patchy areas of lipid accumulation.^{48, 354} Vestibular schwannomas typically enlarge within the cerebellopontine angle cistern and may displace and compress the adjacent pons, medulla, and fourth ventricle. They can attain considerable size before becoming clinically evident. Obstruction of the ipsilateral cerebellopontine angle cistern may occur, with formation of one or more extratumoral arachnoid cysts.^{241, 306} Trigeminal schwannomas tend to occur more commonly in the parasellar region of the middle cranial fossa than in the posterior fossa, although approximately 25% extend through the tentorial notch, involving both fossae.²⁴¹

Microscopic evaluation of a schwannoma typically dem-

onstrates a well encapsulated tumor containing collections of spindle-shaped Schwann cells in both compact cellular (Antoni A) and less cellular, more loosely textured (Antoni B) arrangements.^{48, 354} Histologic variations are commonly encountered in larger tumors, including intratumoral clusters of lipid-laden cells, confluent microcysts and larger cysts, and dilated vascular sinusoids surrounded by foci of hemorrhage.³⁵⁴

The diagnosis of vestibular schwannoma on CT rests on the demonstration of a well circumscribed, globular or ovoid, hypodense to isodense (with respect to the adjacent pons and cerebellum) extraaxial mass in the cerebellopontine angle cistern with its base on the posterior aspect of the petrous temporal bone in the region of the internal auditory meatus. Images displayed in a bone window may demonstrate fusiform widening of the internal auditory canal with erosion of its bony margins. However, soft tissue detail within the cisternal portion of the tumor is often obscured by beam hardening artifacts caused by the adjacent dense cortical bone and pneumatized air cells of the petrous pyramid. Tumors up to about 1 cm in diameter typically demonstrate homogeneous density and homogeneously strong contrast enhancement, but larger tumors often demonstrate heterogeneity of both density and contrast enhancement because of the presence of intratumoral cystic degeneration, xanthomatous change, or intermixed areas of hypercellularity and hypocellularity.^{66, 241, 302}

On MRI, smaller tumors can be more reliably detected, especially within the internal auditory canal, because of the lack of bone induced artifact and the multidimensional capability of this modality. The transition zone between the central (oligodendroglial) and peripheral (Schwann cell) portions of the eighth (vestibulocochlear) nerve, the presumed site of origin of schwannomas of this nerve, occurs within the canal. Tumors less than 5 mm in diameter can be reliably identified on thin section T1-weighted MRI, appearing as homogeneously mildly hypointense or isointense (to adjacent brain) ovoid or tubular intracanalicular masses with intense homogeneous contrast enhancement (Fig. 5-33).^{222, 241, 275, 302, 306} On T2-weighted pulsing sequences, small vestibular schwannomas appear mildly to markedly hyperintense and may be obscured by the similarity in signal intensity to that of the surrounding CSF.¹¹

As these tumors enlarge, the intratumoral degenerative changes previously described cause increasing heterogeneity of signal within the main tumor mass in the cerebellopontine angle cistern.^{241, 302} On axial images, the tumor often has a commalike shape with a globular cisternal mass medially and a short tapered fusiform extension laterally into the internal auditory canal. Contrast enhancement is seen in nearly all schwannomas and may be homogeneous (two thirds of cases) or heterogeneous (see Figs. 5-21, 5-33, and 5-34).^{241, 302, 306} Larger tumors compress and displace the adjacent anterolateral margin of the cerebellar hemisphere posteromedially, displace, compress, and rotate the pons and medulla, and narrow the fourth ventricle, elongating it in the anteroposterior direction (Figs. 5-21 and 5-34). Peritumoral vasogenic edema is frequently observed, and (as noted previously) associated arachnoid cysts are visualized in 5% to 10% of cases.²²²

Vestibular schwannomas represent 80% to 85% of cerebellopontine angle masses.^{275, 306} The major differential di-

Figure 5-33. Vestibular schwannoma. Axial T1-weighted image of the posterior fossa and skull base following intravenous administration of gadolinium. A small intensely enhancing intracanalicular ovoid mass protrudes slightly medially into the cerebellopontine angle cistern on the right (arrow).

Figure 5-34. Bilateral vestibular schwannomas and right trigeminal schwannoma in a patient with neurofibromatosis type 2. Coronal postgadolinium T1-weighted MR image demonstrates three intensely contrast enhancing lesions in the posterior cranial fossa. The large left sided lobulated vestibular schwannoma fills the left cerebellopontine angle cistern (white arrow), compresses, indents and displaces the left lateral margin of the pons inward, and extends laterally into the widened left internal auditory canal. A tiny punctate focus of contrast enhancement in the right petrous temporal region (white arrowhead) represents a small intracanalicular vestibular schwannoma. A third focus of contrast enhancement abuts and indents the right lateral margin of the pons (black arrow); this is a trigeminal (fifth cranial nerve) schwannoma.

agnostic considerations include meningioma and epidermoid tumor.^{241, 275, 306} Meningioma involving the dura of the posterior margin of the petrous temporal bone can project posteriorly into the cerebellopontine angle and simulate a vestibular schwannoma (Fig. 5–35). Such lesions represent about 10% of cerebellopontine angle masses.³⁰⁶ Although meningiomas are typically more dense on CT, these two neoplasms may have identical signal intensity characteristics on MRI. Intense homogeneous or slightly heterogeneous contrast enhancement is another shared characteristic (Fig. 5–35B).²⁷⁵ However, meningiomas are usually situated eccentric to the internal auditory canal and form a more obtuse angle with the petrous ridge than schwannomas.¹⁸¹ Extension of meningioma into the internal auditory canal is uncommon but not unknown,²⁷⁵ and rarely, schwannoma may simulate the appearance of a dural tail on contrast enhanced images.²⁵²

Epidermoid may resemble vestibular schwannoma on noncontrast CT but typically appears more lobulated and more hypodense and tends to insinuate more extensively into the subarachnoid spaces adjacent to the pons without causing major compression of the pons and fourth ventricle. On both CT and MRI, epidermoid does not demonstrate contrast enhancement. On MRI, larger epidermoids appear more homogeneous than schwannomas of similar size and may mimic CSF in intensity, with high T2 signal and low T1 signal.^{11, 275, 306, 322}

Neurofibroma

Neurofibromas are well demarcated infiltrative intraneural or diffusely infiltrative extraneural benign tumors that

consist of a mixture of neoplastic Schwann cells, perineurial cells, and fibroblasts in a collagenous and mucoid matrix.^{241, 354} They are histologically benign and considered WHO grade I. With only extremely rare exception, neurofibromas do not arise within the intracranial portions of the cranial nerves.^{241, 354} However, they can arise peripherally and extend retrogradely into the cranial vault, notably in the facial nerve (CN VII) and the ophthalmic division of the trigeminal nerve (CN V).²⁴¹

The tumors exhibiting this retrograde intracranial extension are usually plexiform neurofibromas, which involve multiple nerve fascicles or trunks with fusiform multinodular enlargement often described as ropelike. On noncontrast CT, they appear isodense with adjacent muscle, and on MRI they are isointense with adjacent muscle on T1-weighted images and hyperintense on T2-weighted images.²⁴¹ Contrast enhancement is variable, with areas of moderate to strong enhancement after IV administration of gadolinium.

Multiple neurofibromas are typically associated with NF1 (also known as von Recklinghausen disease), an autosomal dominant congenital disorder associated with a gene defect on the long arm of chromosome 17.³³⁹ Approximately 50% of patients report no family history and are presumed to represent new spontaneous germline mutations.^{241, 339} In addition to multiple neurofibromas of the spinal and peripheral nerves, NF1 also includes optic nerve and chiasm gliomas, foci of “hamartomatous” change of uncertain etiology in the region of the basal ganglia and in the optic tracts and radiations, cerebral peduncles, and brain stem, astrocytomas of the spinal cord, multiple café au lait spots, axillary and inguinal freckling, malignant

Figure 5–35. Meningioma arising from the posterior aspect of the left temporal bone. **A**, Axial T2-weighted MR image demonstrates a large rounded extraaxial tumor mass in the right side of the posterior fossa with its base on the posterior dura of the left temporal bone. The mass is slightly hyperintense relative to gray matter and compresses and displaces the right cerebellar hemisphere posteriorly and medially. A narrow cleft of cerebrospinal fluid (arrow) separates the medial margin of the tumor from the adjacent compressed cerebellum and pons. Note that the internal auditory canals bilaterally are filled with cerebrospinal fluid. **B**, Following intravenous administration of gadolinium, an axial T1-weighted image demonstrates intense homogeneous contrast enhancement of this large dural-based tumor (arrow).

peripheral nerve sheath tumors, iris hamartomas, and dysplastic osseous lesions (sphenoid wing dysplasia, pencil-like thinning of the long bones).^{223, 321, 339} Patients with NF1 usually present clinically very early in life, whereas those with sporadic solitary neurofibroma involving a cranial nerve may present in later youth and adult life.

On noncontrast CT, plexiform neurofibroma appears as a poorly circumscribed irregular widening of the involved root, which is isodense with adjacent muscles. Erosion of adjacent bone with widening of bony foramina may be evident. MRI demonstrates the widened nerve, which is isointense with adjacent muscle on T1-weighted images and hyperintense on T2-weighted images. Contrast enhancement after IV administration of gadolinium is the rule, varying from moderate to intense.^{25, 241}

Malignant Peripheral Nerve Sheath Tumors

Malignant peripheral nerve sheath tumors are rare tumors that appear to arise *de novo* in the cranial nerves, the fifth cranial nerve being more frequently involved than any other.³⁵⁴ Elsewhere in the body, almost two thirds of reported cases of malignant peripheral nerve sheath tumors have arisen from preexisting neurofibromas, often plexiform and in the setting of NF1.³⁵⁴ Approximately 50% occur in association with NF1. The incidence of malignant progression in patients with plexiform neurofibroma is approximately 5%. Imaging findings include irregularity and loss of clear tumor margins together with inhomogeneous contrast enhancement. Evidence of diffuse invasion of the skull base may also be present.²⁴¹

Tumors of the Meninges

A wide variety of primary tumors can arise from and develop within the meninges.¹⁹⁹ By far the most common is meningioma. Another important meningeal tumor, until 1993 considered a variant of meningioma, is the hemangiopericytoma. Additionally, nonmeningothelial mesenchymal tumors, both benign (lipoma, chondroma, benign fibrous histiocytoma) and malignant (chondrosarcoma, osteosarcoma), can originate in the meninges. Also, tumors of melanocytic origin can rarely arise within the intracranial meninges. Finally, although the histogenesis is uncertain, neuropathologists usually assign hemangioblastomas to this category.

Meningioma

Meningiomas are solid, well circumscribed, highly cellular, slow growing tumors that are usually benign histologically (WHO grade I). These spherical and sometimes lobulated tumors are composed of neoplastic meningothelial cells originating from the arachnoid layer of the meninges with a broad attachment to the adjacent dura. Most commonly, they project inward from the dura, indenting and compressing the underlying brain, causing neurologic symptoms and signs through compression of the adjacent cortex.

Meningiomas are the most common primary extracerebral tumors of the CNS, accounting for approximately 20% of primary brain tumors.^{184, 199} They occur mainly in middle and old age, with a peak incidence in the fifth through seventh decades of life²⁷⁷; these tumors can, however, be found in all age groups. Meningiomas exhibit a strong sex predilection, occurring preponderantly in females, with a female-to-male ratio of at least 2:1.³⁰² However, meningiomas associated with hereditary tumor syndromes, such as NF2, generally occur in younger patients and do not demonstrate a female predilection.¹⁹⁹

Common sites of origin are the frontal and parietal convexities and the parasagittal region, often in close association with the falx cerebri (about 50%), as well as the sphenoid wings, olfactory grooves, sylvian fissures, and parasellar regions (about 35%).^{120, 199} Less than 10% arise below the level of the tentorium, mainly from the clivus, the leaves and free edge of the tentorium, and the petrous pyramid.²⁸² Multiple meningiomas are reported in 6% to 9% of cases,²⁸⁶ occurring both as a component of NF2²²³ and, less commonly, sporadically.

Although most meningiomas are slow growing and well encapsulated globular masses, variations in shape and histology are not unusual. Invasion of the dura and encasement or invasion of the nearby dural venous sinuses are common.¹⁹⁹ Tumors arising in relation to the sphenoid wing are frequently flat (en plaque) and tend to invade through both layers of the cranial dura into the adjacent bone, provoking a notable bony reaction with thickening and sclerosis (meningioma bone).^{120, 277} Such bony changes are a source of considerable controversy; many clinical neuroscientists regard bony sclerosis and thickening as highly indicative of tumor infiltration into the haversian canals of the calvaria,¹⁹⁹ whereas others state that such hyperostosis can also occur without histologic evidence of bone infiltration by tumor.²⁷⁷ Meningiomas arising adjacent to the cribriform plate and planum sphenoidale and those occurring over the high cerebral convexities are more typically rounded and invaginate the underlying brain; however, they also show a propensity for stimulating adjacent bony thickening and sclerosis (Fig. 5-36).¹²⁰

Several different histologic types of meningioma have been described.^{31, 199, 257, 286} A small but significant minority (4% to 8%) of meningiomas are identified as atypical on the basis of increased mitotic activity and high nuclear-to-cytoplasmic ratio. The most aggressive exhibit the histologic features of frank malignancy (anaplastic and malignant meningiomas) and may invade the adjacent cerebral parenchyma.¹⁹⁹ Atypical and anaplastic meningiomas occur more frequently in the high cerebral convexities and the falx. Most meningiomas are homogeneously solid tumors, but foci of necrosis and scarring (probably secondary to ischemia), microcystic change or areas of heavy lipid storage (lipomatous/lipoblastic meningiomas) (see Fig. 5-38) can be identified in approximately 5% to 15% of excised tumors.^{99, 204, 287}

Approximately three quarters of meningiomas appear on noncontrast CT as sharply circumscribed, rounded and sometimes lobulated, homogeneous masses of slightly increased density (40 to 50 HU) compared with adjacent brain.^{5, 40, 233} The hyperdensity is related to the dense cellularity of these tumors and does not reflect psammomatous

Figure 5-36. Sphenoid wing meningioma with underlying hyperostosis (“meningioma bone”). *A*, Axial postcontrast CT image demonstrates intense homogeneous contrast enhancement of a large round extracerebral tumor with its base on the right greater sphenoid wing (arrow). On its inner aspect, the tumor is surrounded by a thick band of hypodensity representing edema of the adjacent cerebral cortex and white matter. There is a marked shift of the midline vessels to the left. *B*, On an axial CT image displayed in a bone window setting, the underlying greater sphenoid wing and squamous portion of the temporal bone demonstrate heterogeneous bony thickening (arrow).

change within the tumor. Meningioma typically has a broad base on a dural surface. The invaginating mass displaces and compresses the underlying brain and causes flattening of the adjacent cerebral cortex (Fig. 5-36A). Inward buckling of the white matter can be identified in about 40% of meningiomas.¹¹³ A hypodense rim (representing trapped CSF) may be insinuated between the invaginating mass and the invaginated cerebral parenchyma; cystic changes in the arachnoid may also be identified adjacent to the tumor margins.²⁸⁷ About 10% of meningiomas appear isodense with the adjacent brain on noncontrast CT,²³³ and an occasional tumor contains areas of hypodensity that correlate pathologically with foci of ischemic scar, microcysts, or lipoblastic change.^{40, 99, 204, 287}

Vasogenic edema of the adjacent cerebral white matter is identified in 50% to 75% of meningiomas.^{5, 302} The mechanism responsible for the occurrence of peritumoral intracerebral edema is uncertain, and there is no correlation between tumor size and extent of edema.²³³ Significant edema is found more commonly in patients with lateral convexity tumors than in those with tumors in other sites.²³³ The occurrence of intracerebral edema appears to correlate with a poorer prognosis, a correlation that may be related to reduced resectability.³⁰² Hyperostosis and thickening of adjacent bone in sphenoid wing, skull base, and high convexity meningiomas, as described previously, can be clearly delineated on CT if high center and wide window settings are employed (Fig. 5-36B).

After IV administration of contrast medium, a meningioma typically displays a striking homogeneous enhancement (increase of 40 to 50 HU or more) (see Fig. 5-36A).^{5, 302} Even the occasional isodense meningiomas exhibit this intense opacification. However, meningiomas that are predominantly microcystic may not enhance strongly or uniformly.¹⁹⁹ In 5% to 15% of cases, focal areas of nonenhancement can be identified within the tumor mass.^{233, 287} These areas have been correlated pathologically with regions of necrosis, old hemorrhage, scarring, cystic degeneration, and lipoblastic change²⁸⁷; they usually do not interfere with the accuracy of diagnosis. Occasionally, however, the heterogeneity of contrast enhancement may be sufficient to raise the question of glioblastoma.^{5, 233, 287}

Parasagittal meningiomas of sufficient size may compress (Fig. 5-37A, B) or invade the adjacent superior sagittal sinus; interruption of the sinus can be identified on coronal postcontrast CT or noncontrast MR images and is an important preoperative finding for which the radiologist must search. Indistinct irregular tumor margins, a mushroomlike extension of opacified tumor well away from the main ovoid tumor mass, and prominent venous drainage centrally from the tumor are CT and MRI signs that may suggest an aggressive anaplastic or malignant meningioma invading the brain.^{234, 295}

In a multiinstitutional prospective study, the sensitivity of contrast enhanced CT for detection of an intracranial mass in patients with meningioma was 96%.²³³ Ten percent

Figure 5-37. Multiple meningiomas. Transcalvarial tumor extension with subgaleal mass and dural tail. Axial T2-weighted (A) and post intravenous gadolinium T1-weighted (B) images demonstrate a large right frontoparietal convexity extracerebral tumor that is homogeneously mildly hyperintense to gray matter on T2-weighting and intensely and homogeneously enhances following intravenous gadolinium. This aggressive tumor extends through the calvaria (black arrow in B) and presents as a broad based mass under the scalp (white arrows in A and B). Note also the presence of a second similar tumor arising in the high posterior falx cerebri on its left lateral aspect and displacing the superior sagittal sinus posterosuperiorly and to the right of the midline. C, Coronal T1-weighted postgadolinium image demonstrates intense homogeneous contrast enhancement of both the convexity and the parasagittal tumors and also of a third large similarly enhancing tumor in the left cerebellopontine angle. Note the “dural tail” of tumor extension over the right frontal convexity (arrow).

of the masses were not detected on the noncontrast scans. The differential diagnosis of a hyperdense or isodense peripherally situated extracerebral mass with homogeneous contrast enhancement includes metastatic malignancy (particularly, carcinoma of the lung and melanoma),^{116, 268} acute leukemia,³⁴⁷ systemic lymphoma,¹¹ and (at the skull base) schwannoma of a cranial nerve.²⁸⁶ Criteria for differentia-

tion are lesion location and configuration, definition of margins, and presence or absence of associated bony changes (erosion or hyperostosis).

On noncontrast MRI, the majority of meningiomas present a homogeneous appearance similar to that seen on CT. Tumor signal intensity on T1-weighted images tends to approximate that of the adjacent cerebral cortex in about

50% of cases and to be hypointense to cortex in 50%. On T2-weighted images, about 50% are mildly hyperintense relative to adjacent gray matter (see Fig. 5-37A) and 50% are isointense with the cortex (see Fig. 5-35A).^{11, 99} On T2-weighted images, comparison of signal intensity of tumor with that of cortex may have histologic correlation; in one reported series, hyperintensity correlated strongly with either syncytial or angioblastic types of meningioma,

whereas fibroblastic and transitional meningiomas failed to demonstrate hyperintensity.⁹⁹ A minority of meningiomas appear heterogeneous on both T1- and T2-weighted images because of the presence of intratumoral lipoblastic or cystic changes (Figs. 5-1A and 5-38A, B), calcifications, or prominent vessels.^{11, 100}

MRI enables more accurate localization and evaluation of these extracerebral tumors than CT. This superiority is

Figure 5-38. Lipoblastic meningioma. Axial T1-weighted (A) and T2-weighted (B) MR images demonstrate a curvilinear focus of T1 hyperintensity in the far right lateral temporooccipital convexity (arrows). The remainder of this dural based extracerebral tumor cannot be clearly distinguished from the adjacent compressed brain parenchyma on the T1-weighted noncontrast image. The lesion (arrow) is also barely discernible on the fast T2-weighted image (B). Following intravenous administration of gadolinium (C), the tumor, which is based on the most lateral aspect of the right leaf of the tentorium, enhances intensely on T1-weighted imaging, except for the focus of lipid storage (arrow).

due not only to the visualization of the mass in all three dimensions and the lack of beam hardening artifact at the base of the brain with MR. In approximately two thirds of cases, the interface between the inner margin of the extracerebral tumor mass and the invaginated or displaced cortex can be recognized on MRI from the presence of a cleft of CSF (see Fig. 5-35A) or the interposition of vascular flow voids of the displaced arteries and veins on the pial surface of the brain (see Fig. 5-1A).¹¹ Also, invasion of adjacent brain by meningiomas arising from the tentorium, the falx, and the dura of the lateral wall of the cavernous sinus can be recognized as a breach in the hypointense dural rim at the tumor margin.¹¹ Finally, arterial encasement and partial dural venous sinus invasion are more readily and accurately depicted by the contrast between the flow void and the tumor tissue.¹¹

As on CT, meningiomas usually demonstrate rapid and pronounced contrast enhancement after IV administration of paramagnetic contrast agent, and the strong, often striking, homogeneous contrast enhancement seen in most meningiomas enables their accurate detection and localization (Figs. 5-1B, 5-35B, 5-37B, C, 5-38C, and 5-39B).^{11, 158, 275}

A thickened tapered extension of contrast enhancing dura is commonly identified at the margins of the tumor (Fig. 5-35C). This *dural tail* may indicate the presence of tumor infiltration¹²¹ or may be due to dural reaction.²²⁵ Because a major prognostic factor in the recurrence of meningiomas after surgery is the extent of tumor resec-

tion,¹⁹⁹ careful assessment must be made of preoperative postcontrast MR images for the presence of a dural tail.

The arachnoid contributes embryologically to the formation of the choroid plexuses, so intraventricular meningiomas may arise within the choroid plexus of the lateral ventricle and locally expand the ventricle to conform to the size and shape of the tumor (Fig. 5-39).^{221, 300, 302} These tumors share the imaging characteristics of extracerebral meningiomas as previously described. The normally compact choroid glomus calcifications may be fragmented and spread by the expanding tumor mass.³⁰⁰ Differentiation from choroid plexus papilloma is based on (1) patient age (papillomas of the lateral ventricles occur mainly in infants and very young children), (2) tumor surface characteristics (papillomas tend to have a nodular irregular margin, whereas meningiomas tend to be smoothly rounded), and (3) size and shape of the cerebral ventricles (papillomas are often associated with diffuse enlargement of all ventricles, whereas meningiomas cause only focal enlargement).¹¹

Hemangiopericytoma

Hemangiopericytoma is now recognized in the WHO classification of tumors of the CNS as a distinct entity separate from meningioma.¹⁴⁷ This dural based tumor was formerly considered an "angioblastic" meningioma be-

Figure 5-39. Intraventricular meningioma. A, A large round mildly hyperintense (to gray matter) tumor fills and distends the atrium of the right lateral ventricle (arrow) on this axial T2-weighted MR image. Note the dilatation of the anterior right temporal horn proximal to the obstruction caused by this mass. Edema of the surrounding white matter contributes to the right sided mass effect, which causes compression of the right frontal horn and marked shift of the septum pellucidum to the left of the midline. B, An axial T1-weighted postgadolinium image demonstrates intense homogeneous contrast enhancement of this large multilobulated intraventricular meningioma (arrow).

cause of its hypervascularity. However, despite many gross pathologic, histopathologic, and imaging similarities to meningioma, the aggressive clinical behavior of hemangiopericytomas differs considerably from the majority of meningiomas, and it is now possible to distinguish the two entities immunohistochemically.¹⁴⁷ The cell of origin is the pericyte, a perivascular cell of mesenchymal origin, and the intracranial tumors are identical histologically to their counterparts in the somatic soft tissues.¹⁴⁷

Like meningiomas, hemangiopericytomas are dural based, extraaxial rounded masses, well circumscribed and highly cellular. They are often more lobulated in contour than the typical meningioma and are more commonly located in the occipital region near the confluence of the dural venous sinuses, to which they are often attached.¹⁴⁸ They are comparatively rare, with a ratio of 1 hemangiopericytoma to 40 or 50 meningiomas.^{129, 148} They tend to occur in younger patients, typically in their 40s, and the sex distribution (male-to-female ratio = 1.4:1) differs markedly from that of meningiomas.¹⁴⁷

Histologically, hemangiopericytomas appear highly cellular with moderate nuclear atypia and prominent mitotic activity comparable to that of anaplastic meningiomas.¹⁴⁷ They are richly vascular tumors with arterial supply from both the meningeal and cerebral arteries, and numerous large and branching vascular channels ("staghorn sinusoids") with perivascular fibrosis are a prominent microscopic finding.¹⁴⁷ Invasion and destruction of overlying bone is not unusual, but these tumors do not provoke a hyperostotic ("meningioma bone") response. Infiltration of underlying brain parenchyma can also occur. Hemangiopericytomas exhibit a marked tendency to recur locally despite apparently complete surgical excision and postoperative irradiation of the former tumor bed; in one large series, the 15 year recurrence rate was 85%.¹²⁹ They also tend to metastasize beyond the cranial cavity; in the same large series,¹²⁹ 60% of tumors had metastasized after 15 years, mainly to bone, lung, and liver.

The findings on diagnostic imaging tend to mimic those of meningiomas. These sharply circumscribed extraaxial masses appear hyperdense on noncontrast CT and are generally homogeneous and hypointense to white matter and isointense with gray matter on T1-weighted noncontrast MRI (Fig. 5-40A). On T2-weighted images, hemangiopericytomas typically are slightly hyperintense and more heterogeneous in appearance (Fig. 5-40B). As noted previously, hemangiopericytomas often appear more lobulated and exhibit a higher incidence and degree of heterogeneity of attenuation (CT) and signal intensity (MRI) than meningiomas owing to the presence of multiple flow voids.³⁰² Contrast enhancement of hemangiopericytomas is usually intense and homogeneous (Fig. 5-40C). Points of differentiation from meningioma include a greater frequency of internal heterogeneity and external lobulation, a tendency toward a more narrow base of dural attachment, and absence of tumor calcification and hyperostosis of adjacent bone.⁵³

Mesenchymal Nonmeningothelial Tumors

A diverse group of relatively rare tumors, mesenchymal nonmeningothelial tumors may arise within the cranial

vault, either in the skull base, the calvaria and sutures, the meninges, or (most rarely) within the cerebral parenchyma. They may be of primitive mesenchymal origin but have not differentiated along the meningotheial line. Rather, these unusual lesions exhibit fibrous, fibrohistiocytic, adipose, myoid, endothelial, chondroid, or osseous differentiation and cannot be distinguished histologically from their more common counterparts in the somatic soft tissues.²⁵¹

These tumors vary widely in location, histology, pathologic grade, and clinical behavior. Some (e.g., lipomas and hemangiomas) are benign (WHO grade I) and mainly asymptomatic, and some (e.g., osteosarcomas and rhabdomyosarcomas) are highly malignant (WHO grade IV) and highly invasive. Tumors arising in the meninges are more common than those originating within cerebral parenchyma. Although most of these lesions occur supratentorially in adults, many rhabdomyosarcomas occur below the tentorium in young children. Lipomas typically occur in or near the midline and are associated with malformations of the corpus callosum, whereas chondrosarcomas arise most commonly in the skull base off the midline (e.g., the petroclival suture).

Lipomas are not true neoplasms but instead likely represent congenital malformations.³⁵⁶ They enlarge only with somatic growth. Intracranial lipomas are usually subarachnoid in location and occur most commonly in the pericallosal sulcus. Other sites are the chiasmatic, circummesencephalic, interpeduncular, and quadrigeminal cisterns and, in the posterior fossa, the cerebellopontine angle cistern.¹¹ More than 50% of pericallosal lipomas are associated with partial agenesis or dysgenesis of the adjacent corpus callosum, with the rostrum, genu, and anterior portion of the body more commonly affected than the posterior body or splenium.³⁵⁶

Two types of pericallosal lipomas are recognized. The tubonodular lipomas are large and rounded, are located anteriorly, and have a high incidence of associated corpus callosal dysgenesis as well as anomalies of the frontal lobes.²³⁹ The curvilinear type tend to be more posteriorly situated, appear long and thin, curve around the splenium, and are associated with a normal or only slightly dysgenetic corpus callosum (Fig. 5-41).²³⁸ These lesions are tightly adherent to the adjacent brain, and lipoma in the cerebellopontine angle cistern may envelop and compress the seventh and eighth cranial nerves where they pass through the cistern.⁶⁷

Lipomas are typically asymptomatic and discovered only incidentally when the head is imaged for other reasons. Even on plain skull radiographs, the tubonodular masses are recognized from their well demarcated homogeneous lucency in the midline anteriorly, often associated with marginal curvilinear calcification bilaterally (see Fig. 5-41). On CT scans, the smoothly demarcated mass appears more hypodense than CSF (-50 to -100 HU) and is often marginated laterally by nodular or curvilinear calcification (see Fig. 5-41). On MRI, lipomas appear mainly homogeneously hyperintense on both T1-weighted and fast spin-echo T2-weighted images, but areas of low signal, secondary to the marginal calcification, are commonly noted peripherally.¹¹⁴ Central flow voids, representing pericallosal arteries coursing through the substance of the tumor, are prominent within the tumor mass.

Figure 5-40. Hemangiopericytoma in the floor of the posterior cranial fossa on the right. Axial T1-weighted (A) and T2-weighted (B) MR images. A large well circumscribed lobulated homogeneously hypointense (T1-weighted)/hyperintense (T2-weighted) extraaxial mass (arrows) deeply invaginates and displaces the inferior aspect of the right cerebellar hemisphere and vermis medially across the midline and indents the right posterolateral aspect of the medulla. C, Following intravenous administration of gadolinium, intense homogeneous contrast enhancement is noted in this lobulated tumor (arrow).

Osteocartilaginous tumors occasionally arise within dural structures such as the falx. The CNS is the most common site of occurrence of extraosseous *chondrosarcoma*.²⁵¹ This mesenchymally derived malignancy occurs more frequently in the skull base, notably in the region of the intrasphenoid synchondrosis or the adjacent petroclival suture, and it may invade the overlying brain (Fig. 5-42). Whether arising from dura or from skull base structures,

chondrosarcomas manifest as soft tissue masses with focal bone destruction. Intratumoral calcifications, identified in about half of tumors, contribute to a heterogeneous appearance on MRI, with intratumoral nodules which appear hypointense to isointense with adjacent brain on T1-weighted images and hyperintense to brain on T2-weighted images.²¹⁶ Intense contrast enhancement of the soft tissue mass is the rule (Fig. 5-42B).

Figure 5-41. Pericallosal lipoma and partial agenesis of the corpus callosum. Axial noncontrast CT image demonstrates widely separated and parallel bodies of the lateral ventricles with an intervening elevated and dilated third ventricle (*black arrow*); these findings are consistent with partial agenesis of the anterior portion of the corpus callosum. In the midline more posteriorly, a markedly hypodense rhomboid-shaped curvilinear lipoma (*white arrow*) with two internal foci of calcification separates the lateral ventricles.

Figure 5-42. Chondrosarcomas of the skull base. *A*, Axial noncontrast CT image displayed in a bone window demonstrates bilateral irregularly margined areas of bone destruction in the region of the intrasphenoid synchondrosis with multiple intratumoral hyperdensities representing foci of calcification and/or bony sequestra. The bony destruction involves the right lateral margin of the clivus (*arrow*) and the right petrous apex. *B*, In another patient, an axial CT image following intravenous contrast displayed in a soft tissue window demonstrates more extensive bone destruction involving the entire body of the sphenoid bone, the right ethmoid sinus, and the right orbit with foci of intratumoral calcification and/or bony sequestra. The soft tissue components of this tumor demonstrate heterogeneous contrast enhancement (*arrow*) with multiple ill defined areas of nonenhancement.

Other mesenchymal malignancies may also rarely originate within the cranial vault but more commonly arise in extracranial structures and secondarily invade the skull and brain, notably the *embryonal rhabdomyosarcoma*.^{237, 251} This is the most common soft tissue sarcoma in children, and the head and neck are the most common site of occurrence, especially the orbit and the nasopharynx as well as the middle ear.²³⁷ The tumor is almost uniformly fatal within 2 years of presentation, despite intensive chemotherapy and radiotherapy.²⁵¹ An extremely aggressive neoplasm, embryonal rhabdomyosarcoma commonly invades through the skull base into the adjacent brain. Evidence of invasion of the anterior skull base, the cavernous sinuses, or both is identified on MRI in 35% of embryonal rhabdomyosarcomas originating in the nasopharynx.¹⁸⁰

Perineural and meningeal spread of tumor is also common in this tumor.²³⁸ Imaging studies demonstrate large soft tissue masses with evidence of aggressive bone destruction. On MRI, these lesions appear isointense with muscle on T1-weighted images and hyperintense to brain and muscle on T2-weighted images, findings that are non-specific and similar to those seen in nasopharyngeal carcinoma, myeloma, and neuroblastoma.^{180, 237} Embryonal rhabdomyosarcomas exhibit contrast enhancement, which varies in both extent and intensity.

Melanocytic Tumors

A wide spectrum of tumors of melanocytic origin, varying from benign and diffuse (melanocytosis) to benign and well circumscribed (melanocytoma) to malignant (primary malignant melanoma), can originate within the meninges and the CNS.¹⁵¹ They are thought to arise from leptomeningeal melanocytes derived from the neural crest. These tumors are all uncommon lesions, but the benign forms are less rare than the primary malignancies.

Melanocytomas of the meninges, which represent less than 0.1% of all brain tumors, present as solitary solid, round or flat extraaxial masses occurring mainly near the foramen magnum or in the region of Meckel's cave. Histologically, they demonstrate monomorphic cells with variable melanin content in their cytoplasm and a low mitotic rate.¹⁵¹ Immunohistochemical studies show most tumors reacting to antimelanosomal antibody.¹⁵¹ Presenting symptoms are those related to local compression of the underlying brain or obstruction of CSF flow. They can be found in patients of all age groups, with a peak incidence in the fifth decade of life.¹⁵¹ Females are affected more commonly than males, with a reported 2:1 ratio.²²⁷ On MRI, melanocytomas of the meninges appear as well-circumscribed extraaxial masses that are isointense to hyperintense, depending on the quantity of melanin in the tumor cells on T1-weighted images and hypointense to gray matter on T2-weighted images. Like the majority of meningeal tumors, they exhibit homogeneous contrast enhancement.^{196, 338}

Hemangioblastoma

Hemangioblastomas are benign (WHO grade I) vascular neoplasms of uncertain origin that consist of abundant

endothelial pericytes forming a rich capillary network intermixed with vacuolated (lipid-containing) stromal cells.³² Although relatively uncommon overall (1% to 2.5% of all primary CNS tumors), hemangioblastoma is the most common primary intraaxial posterior fossa tumor in adults.^{168, 186, 286} The great majority (80% to 85%) of CNS hemangioblastomas occur in the cerebellum, 2% to 3% in the medulla, and only 1% to 1.5% above the tentorium.^{142, 286} The remainder (10% to 15%) arise within the spinal cord.¹⁴²

Seventy-five percent to 85% of hemangioblastomas are sporadic in occurrence and solitary. They typically present clinically in young adults with peak incidence in the third to fifth decades of life and are rare in children. The natural history is that of a slow growing mass in the cerebellum that is frequently associated with a cyst. Approximately 60% of these tumors are cystic at the time of clinical presentation.¹⁴² Symptoms are usually related to obstruction of CSF flow in the fourth ventricle by the solid tumor or the associated cyst.³² Hemorrhage is uncommon in hemangioblastoma despite the prominent vascularity, and necrosis is rare. The advent of microsurgical excision techniques has significantly improved the prognosis in patients with sporadically occurring hemangioblastomas; mortality is low, and permanent neurologic deficits are rare.³²

On gross inspection, hemangioblastomas are well demarcated, highly vascularized, small (5 to 10 mm), rounded solid lesions located peripherally within the cerebellum, brain stem, or spinal cord, usually abutting a pial surface (Fig. 5-43).^{32, 104} The most striking lesions are those associated with well circumscribed cysts in which the solid tumor is a mural nodule.²⁸⁶ Like the cyst associated with juvenile pilocytic astrocytoma of the cerebellum with a mural nodule, the cyst associated with a hemangioblastoma is essentially extratumoral, lacking any tumor tissue in its margin except for the eccentrically located solid nodule.²⁸⁶ The cyst wall is composed of compressed brain parenchyma or reactive gliosis.¹⁴²

Approximately 25% of hemangioblastomas are associated with von Hippel-Lindau disease, a phakomatosis that is inherited as an autosomal dominant trait caused by a germline mutation of a suppressor gene on the 3p chromosome.³² Lindau¹⁹⁴ originally described this disease complex in 1926; it is characterized by the development of capillary hemangioblastomas in the CNS in association with identical tumors in the retina (originally described by von Hippel³⁴⁰ in 1906); clear cell renal carcinomas, pheochromocytomas, and pancreatic, renal, and hepatic cysts are also frequently found in patients with the disease.

Multiplicity of hemangioblastomas of the cerebellum, brain stem, and spinal cord is common (10% to 40% of cases) in patients with von Hippel-Lindau disease,¹⁰⁴ and multiple tumors are found almost exclusively in patients with the disease (Fig. 5-44).^{32, 232} Patients with von Hippel-Lindau disease become symptomatic at an earlier age (mean age at diagnosis, 29 years) than those with solitary sporadically occurring tumors.³² Despite improved surgical techniques, the most common cause of death in patients with von Hippel-Lindau disease is hemangioblastoma.¹⁵⁷

Noncontrast CT scans usually demonstrate a large, sharply marginated, hypodense, cystic cerebellar hemi-

Figure 5-43. Hemangioblastoma of the cerebellum. *A*, A coronal T2-weighted MR image demonstrates a sharply margined ovoid hyperintense mass in the superior aspect of the left cerebellar hemisphere. On the superior margin of this cystic mass, a flat nodule that is isointense to adjacent gray matter is identified (*arrow*). *B*, Following intravenous administration of gadolinium, a coronal T1-weighted image demonstrates intense homogeneous contrast enhancement of the mural nodule (*arrow*), which is located on the superior surface of the cerebellum. The adjacent cyst is hypointense, and its margins do not demonstrate contrast enhancement.

spheric mass with a slightly more dense rounded mural nodule. There is typically little or no peritumoral edema, and the solid lesion or mural nodule may not be distinguishable from surrounding normal cerebellar parenchyma, particularly if the lesion is located inferiorly within the posterior fossa, where it may be masked by dense adjacent bone and beam hardening artifact.¹⁵⁷ Calcifications have not been detected in these tumors.¹⁶⁸ After IV administration of a contrast agent, the solid tumor or mural nodule enhances homogeneously and intensely adjacent to a pial surface.²⁴¹ Because of the intense vascularity of even the smallest solid tumor nodules, angiography may be more sensitive than CT or MRI in the detection of hemangioblastoma.

On MRI, the cysts typically are sharply and smoothly margined and homogeneously hypointense relative to adjacent brain parenchyma on T1-weighted images and hyperintense on T2-weighted images (Fig. 5-43A).^{142, 241} The solid tumors and mural nodules are usually inhomogeneous in signal pattern but predominantly isointense with normal gray matter on T1-weighted images and slightly hyperintense on T2-weighted images. Areas of increased signal within the nodule or the cyst on T1-weighted images are occasionally noted secondary to hemorrhage.^{142, 168, 186} Serpentine signal voids due to enlarged vessels supplying and draining the tumor may be identified at the periphery of the mass or nodule, a finding that should strongly suggest the diagnosis in the appropriate clinical setting.^{186, 241} As with CT, contrast enhancement of the solid tumor or mural nodule on T1-weighted MRI is characteristically homogeneous and intense (see Figs. 5-43B and 5-44).^{10, 142, 241}

Tumors of the Hematopoietic System

During the last two decades of the 20th century, tumors and tumor-like conditions of the hematopoietic system involving the CNS increased in both frequency and clinical and societal significance. Most notable in this regard was a greater than 10-fold increase in incidence of primary CNS non-Hodgkin's lymphoma in the United States.²¹⁷ The vast majority of these tumors are malignant B-cell lymphomas, which carry a poor prognosis.²⁴⁹ Their site of origin is unknown, because the normal brain lacks lymphatics and lymphoid tissue. The rise in incidence of these tumors has been associated with the human immunodeficiency virus (HIV) epidemic; up to 10% of patients in the terminal stages of acquired immunodeficiency syndrome (AIDS) experience an Epstein-Barr virus-associated B-cell malignant cerebral lymphoma.²⁴⁹ The concomitantly growing number of non-HIV-positive immunocompromised patients who have primary cerebral lymphoma, notably those undergoing long term immunosuppressive therapy after allograft organ transplantation, has also contributed to the higher incidence of primary CNS lymphoma.^{10, 143, 254, 286}

Lymphomas arising systemically may involve the brain and meninges secondarily. They include T-cell lymphoma, plasmacytoma, angiotropic lymphoma, and Hodgkin's disease. In current practice, secondary involvement of the CNS by systemic lymphoma is much less common than the primary intracranial malignant B-cell variety.²¹⁷

A heterogeneous group of tumors and tumor-like pro-

cesses of histiocytic origin rarely involve the brain, notably Langerhans cell histiocytosis.²⁵⁰ Although the leukemias in their advanced stages may involve the meninges, leading to detection of malignant cells on CSF cytology, radiologically detectable dural based or intracerebral masses are rare.²⁴⁸

Primary Central Nervous System Lymphoma

Primary malignant lymphomas of the CNS are extra-nodal tumors arising in the CNS in patients with no obvious lymphoma outside the nervous system at the time of initial diagnosis.²¹⁷ Historically, this entity constituted about 1% of all primary tumors of the CNS; by the early 1990s, however, this proportion had increased to 6.6%,²¹⁷ mainly as a consequence of the AIDS epidemic. The incidence of this neoplasm in the AIDS population (4.7 per 1000 person-years) is approximately 3600 times that in the general population.⁷³ Approximately 10% of patients with AIDS experience primary CNS lymphoma, mainly during the late stages of their illness.⁵⁵ In transplant recipients who are immunosuppressed, the incidence of primary CNS lymphoma exceeds 20%.²⁵⁵

Primary CNS lymphoma affects all ages, but the peak incidence in immunocompetent individuals is in the sixth and seventh decades. In patients who have AIDS or have received organ transplants and are receiving immunosuppressive therapy, the median age of onset is in the late 30s. This tumor shows a definite sex predilection, with a 3:2 male-to-female ratio in immunocompetent patients and a 9:1 ratio in patients with AIDS.²¹⁷ The presenting symptoms and signs are nonspecific; focal neurologic deficits are most common, but seizures, signs of increased intracranial pressure, neuropsychological symptoms, and visual disturbances are also frequent.²¹⁷ Primary CNS lymphoma carries a guarded prognosis in immunocompetent patients and a poor prognosis in immunocompromised and immunosuppressed patients. In immunocompetent patients, the initial response rate to radiotherapy, chemotherapy, or both is 85%, but the survival rate is 40% to 70% at 2 years and 25% to 45% at 5 years; in patients with AIDS, the median survival after multimodal therapy is 13.5 months.²¹⁷

On gross inspection, primary CNS lymphoma presents as one or more (usually multiple) firm or friable, centrally located, deep seated masses with variable demarcation from adjacent cerebral parenchyma. The tumors are often located

in close proximity to the ventricles and may infiltrate through and along the ependymal ventricular walls (Fig. 5-45).⁷⁰ The corpus callosum and the basal ganglia are common sites of involvement. Intratumoral hemorrhage and necrosis are uncommon, and peritumoral edema is usually mild in immunocompetent patients, but in immunocompromised patients, lesion growth is more rapid, hemorrhage and necrosis are much more common, and edema of the surrounding white matter is often extensive.^{70, 217} Involvement of the leptomeninges is a common but late finding.

Histologically, 98% of primary CNS lymphomas are high grade B-cell tumors that characteristically demonstrate an angiocentric infiltration pattern, in which collars of small neoplastic lymphocytes surround and infiltrate the walls of the small penetrating vessels of the brain and the perivascular (Virchow-Robin) extensions of the subarachnoid space.^{70, 217} From these perivascular foci, tumor cells invade the adjacent neural parenchyma and coalesce, forming diffuse masses. In AIDS-associated cases, the diffuse masses tend to be multifocal with intervening areas of necrosis.^{70, 217}

CT shows that the tumor masses involve the deep gray matter structures, the periventricular white matter, and the corpus callosum; they appear homogeneously isodense to moderately hyperdense (reflecting dense packing of small tumor cells with a high nuclear-to-cytoplasmic ratio), have relatively ill defined margins, and demonstrate diffuse strong homogeneous contrast enhancement (see Fig. 5-45).^{10, 149, 241, 310} Peritumoral edema is less extensive than that seen in association with primary gliomas and metastases of similar size.¹⁰ Central necrosis with peripheral ring-like contrast enhancement is uncommon in immunocompetent patients but is noted more frequently and involves wider areas with larger lesions in immunocompromised patients.^{10, 149, 241} Extension along the ventricular walls with ependymal contrast enhancement (Fig. 5-45C) and leptomeningeal tumor spread, with hyperdensity in and contrast enhancement of the cisterns and sulci, are common late findings.¹⁴³

On MRI, the deeply seated tumor nodules exhibit a variable signal intensity pattern. Most often, the tumors are homogeneously isointense with gray matter on both T1- and T2-weighted images, findings that are similar to those for other small cell hypercellular tumors.^{10, 241, 279} However, some lesions may exhibit marked T2 hyperintensity. Almost all primary CNS lymphomas demonstrate intense contrast enhancement after IV administration of gadolin-

Figure 5-44. Multiple hemangioblastomas in a patient with von Hippel-Lindau disease. *A*, Axial T1-weighted MR image following intravenous administration of gadolinium demonstrates a sharply defined round homogeneously contrast enhancing nodule on the dorsal aspect of the lower medulla (arrow). Note the absence of a surrounding cyst. *B*, Axial T1-weighted postgadolinium image at the level of the suprasellar cistern. A large lobulated homogeneously intensely contrasting hypothalamic tumor protrudes inferiorly, filling and distending the suprasellar cistern (arrow) and insinuating into the interpeduncular cistern with spreading apart of the cerebral peduncles. Intratumoral hypointense linear and round foci likely represent flow voids within the rich tumor vasculature. This is a most unusual location for a hemangioblastoma. Also, the comparatively large size of this mass without an associated cyst is unusual. *C*, Axial T1-weighted postgadolinium image of the orbits and anterior brain obtained with fat saturation. A relatively large contrast enhancing nodule is identified within the lateral aspect of the left globe (arrow); a partially intranodular cyst is visualized anteriorly. *D*, Coronal T1-weighted postgadolinium image of the thoracic spine demonstrates an elongated nodular homogeneously enhancing tumor located eccentrically within the lower thoracic spinal cord on the right and protruding into and widening the right lateral subarachnoid space (arrow); the differential diagnosis of this lesion would include meningioma, schwannoma, and leptomeningeal metastasis.

Figure 5-45. Primary central nervous system lymphoma in a patient with AIDS. *A*, Axial CT image demonstrates bandlike hyperdensity in the subependymal white matter at the margins of the frontal horns of both lateral ventricles (arrows) with surrounding peritumoral edema. *B*, Following intravenous administration of contrast medium, diffuse enhancement of the periventricular tumor is noted (arrows). *C*, Axial postcontrast CT image at a slightly higher level demonstrates symmetrical subependymal tumor enhancement with surrounding white matter edema along the margins of the frontal horns (arrows), atria and occipital horns of both lateral ventricles, and the lateral margins of the third ventricle.

ium. In immunocompromised patients, this enhancement is often ringlike (reflecting central necrosis) and associated with extensive peritumoral edema, and the clinical and radiologic presentation can simulate that of toxoplasmosis, a common occurrence in patients with AIDS.⁹⁰ The differential diagnosis favors toxoplasmosis if there is associated hemorrhage, whereas the presence of subependymal extension with contrast enhancement of the ventricular walls

favors lymphoma.¹⁰ In such circumstances, a short trial of anti-*Toxoplasma* therapy followed by evaluation of the clinical and imaging response may be sufficient to avoid invasive biopsy.

Leptomeningeal seeding occurs in up to 60% of patients with primary CNS lymphoma, generally late in the course of the disease. Although malignant cells may be readily detected on CSF cytology, detection of subarachnoid tumor

spread on imaging studies has been problematic. Imaging verification of leptomeningeal neoplasm, which is visible as parallel linear streaklike contrast enhancement, may be more easily and reliably detected on T1-weighted postgadolinium MRI than on contrast enhanced CT.^{143, 318}

An unusual form of presentation of primary CNS lymphoma simulates diffuse white matter disease, with patchy and diffuse infiltration of deep white matter as well as deep gray matter. Poorly marginated areas of T2 hyperintensity are seen scattered through the deep cerebral white and gray matter and in the pons. The pattern is similar to that of gliomatosis cerebri. This entity has been termed *lymphomatosis cerebri*.²⁴¹

In an immunocompetent patient, the differential diagnosis of solitary or multiple deep seated tumors that are relatively homogeneous, appear isointense with gray matter on MRI and hyperdense on CT, and demonstrate dense contrast enhancement with mild surrounding edema would include, in addition to primary CNS lymphoma, high grade glioma (e.g., anaplastic astrocytoma), sarcoid, and intraventricular meningioma.

Secondary CNS Lymphoma

Approximately one third of patients with systemic lymphoma demonstrate secondary brain or spinal involvement.²¹ The majority of secondary CNS lymphomas are T-cell lymphomas with a propensity to first involve the leptomeninges surrounding the brain and then extend into cerebral parenchyma along the Virchow-Robin spaces in the periphery of the cerebral hemispheres. Both focal and diffuse thickening of the arachnoid occurs, and infiltration also extends into the overlying dura. As in the primary CNS lymphomas, multicentricity is common, but the masses are predominantly peripherally rather than deeply situated. Thick plaques of tumor on the brain surface that are isointense with the adjacent brain on T1- and T2-weighted images and demonstrate homogeneous contrast enhancement (Fig. 5-46) may simulate the appearance of meningioma; in general, the tumor masses of lymphoma are more numerous and more extensive than those of meningioma and often extend into the subarachnoid space and underlying brain parenchyma.¹⁰

Histiocytic Lesions

Histiocytic lesions represent a heterogeneous group of tumors and tumor-like masses of the brain of unknown etiology that are composed of histiocytes (macrophages) and are often but not always associated with histologically identical extracranial lesions.²⁵⁰ The most common of these disorders is *Langerhans cell histiocytosis (LCH)*, a disease that usually occurs in children and causes solitary (eosinophilic granuloma) or multifocal (Hand-Schüller-Christian) osteolytic lesions of the skull base and membranous skull.¹²⁶ In the multifocal form, there is often irregularly marginated bone destruction in the region of the sella turcica with associated thickening of the pituitary stalk and hypothalamus. The lesions, whether in brain or in bone, appear to be granulomatous infiltrates composed mainly of

Langerhans cell histiocytes in an admixture of lymphocytes, macrophages, plasma cells, and eosinophils.²⁵⁰ Very rarely, multiple foci of demyelination and gliosis with minimal or no granular parenchymal infiltrates may be found within the cerebral or cerebellar white matter in patients with cranial and extracranial LCH; these appear as small poorly marginated areas of hypodensity on CT scans and of hyperintensity on T2-weighted MR images (Fig. 5-47).²⁵⁹

Leukemia

Granulocytic sarcoma (formerly known as *chloroma*) is a focal collection of leukemic cells that form a solid mass projecting inward from the meninges or within the brain parenchyma contiguous with the ventricular wall ependyma in patients with systemic leukemia, typically acute or chronic myelogenous leukemia.^{117, 127, 241} In approximately one third of cases, the tumor may actually precede the development of the systemic disease.¹¹⁷ On CT, the lesion appears hyperdense or isodense relative to brain parenchyma with unsharp margins. On MRI, it demonstrates heterogeneous isointensity or hypointensity relative to gray matter on T1-weighted images and isointensity to hyperintensity on T2-weighted images. Homogeneous contrast enhancement of the tumor is the rule (Fig. 5-48).^{117, 127, 248}

Germ Cell Tumors

Tumors arising from primordial germ cells represent only 0.3% to 0.5% of all primary intracranial neoplasms, although in Asia the figure is 2%.²⁸⁴ Germ cell tumors represent about 3% of primary pediatric intracranial neoplasms, except in Asia, where the proportion has been reported as 10% to 15%.²¹² These tumors are the intracranial morphologic homologues of germinal neoplasms arising in the gonads and in other sites. They present mainly in children and adolescents, with an age peak of 10 to 12 years.²⁸⁴ Approximately 90% arise in patients younger than 20 years with a strong (2:1) male predilection.

Intracranial germ cell tumors occur mainly in or near the midline in the vicinity of the third ventricle. The most common sites of occurrence are the pineal region (65%) and the suprasellar region (30%).¹⁵⁴ Nearly two thirds (65%) of intracranial germ cell neoplasms are germinomas, the intracranial morphologic equivalent of the testicular seminoma, whereas 16% represent teratomas, 6% are endodermal sinus (yolk sac) tumors or embryonal cell carcinomas, 4% are choriocarcinomas, and the remaining 9% are mixed tumors incorporating elements of two or more germ cell types.²⁵⁰ These lesions may be multifocal with involvement of both the pineal and suprasellar regions.

The clinical presentation depends on the location of the tumor mass.²⁸⁴ Patients with pineal region tumors typically present with complaints of headache, because the tumor compresses and obstructs the aqueduct, causing a noncommunicating hydrocephalus. Compression on or invasion of the quadrigeminal plate causes a Parinaud syndrome, with paralysis of upward gaze and convergence. Tumors in the floor of the third ventricle or the suprasellar region typi-

Figure 5-46. Systemic lymphoma with secondary central nervous system involvement. A, An ill defined isointense (with gray matter) mass involves the right posterior temporooccipital convexity cortex (*arrow*) and the adjacent white matter on this axial T1-weighted MR image. B, An axial T2-weighted image at the same level demonstrates a multilobulated right temporooccipital convexity tumor with extensive surrounding edema. Like a meningioma, this heterogeneous tumor is based on the convexity dura, but the deep extension (*arrow*) suggests spread into the cerebral parenchyma via the perivascular (Virchow-Robin) spaces. There is extensive edema of the adjacent forceps major white matter resulting in considerable mass effect with compression of the right sylvian fissure and atrium of the right lateral ventricle, bowing of the third ventricle across the midline, and effacement of the sulci of the right temporal and occipital lobes. C, Following intravenous administration of gadolinium, an axial T1-weighted image demonstrates heterogeneous contrast enhancement in this peripheral multilobulated tumor (*arrow*).

cally impinge upon the optic chiasm (causing visual field defects) or the hypothalamic-pituitary pathways (causing diabetes insipidus, growth retardation, or precocious puberty).

Examination of the serum and CSF for the presence of certain oncoproteins elaborated by germ cell tumors often provides valuable differential diagnostic information and is

also useful in monitoring the course of treatment.²⁸⁴ Elevation of placental alkaline phosphatase (PLAP) in these fluids favors the diagnosis of germinoma, whereas a rise in concentration of alpha-fetoprotein (AFP) suggests the presence of yolk sac endoderm, as in an endodermal sinus (yolk sac) tumor or an immature teratoma. Human chorionic gonadotropin (β -HCG) is elaborated by syncytial tro-

Figure 5-47. Langerhans cell histiocytosis of the hypothalamus and pituitary stalk. *A*, Axial T2-weighted MR image displays a large ill defined area of hyperintensity (likely representing edema) in the region of the hypothalamus (arrow). Within this hyperintensity can be seen two smaller isointense (with gray matter) foci. *B*, Coronal T1-weighted postgadolinium image demonstrates homogeneous contrast enhancement of the two foci; the larger lesion (arrow) extends into and widens the pituitary stalk.

Figure 5-48. Granulocytic sarcoma (formerly known as chloroma) involving the left orbit and cavernous sinus. *A* and *B*, Axial CT images following intravenous contrast administration. In *A*, a sharply outlined irregular contrast enhancing mass is seen in the lateral aspect of the left orbit (arrow). The mass slightly displaces the superior aspect of the left globe and the composite density of the levator palpebrae superioris and superior rectus muscles medially. At a slightly lower level (*B*), the tumor extends into and diffusely widens the left cavernous sinus (arrow).

phoblasts, and elevation of this marker points to the presence of choriocarcinoma.

There is a higher risk of intracranial and mediastinal germ cell tumors in patients with Klinefelter syndrome, a complex chromosomal disorder with a 47XXY karyotype. The most common cause of hypogonadism in young males, Klinefelter syndrome is characterized by testicular atrophy, gynecomastia, and lack of secondary sex characteristics.^{152, 284} Affected individuals are also at greater risk for development of breast carcinoma. Histopathologic examination of tumor tissue is essential for treatment planning and prognosis.^{102, 284} Although germinomas and teratomas often occur as pure tumor types, the nongerminomatous neoplasms are often of mixed cellular composition, and immunohistochemical studies performed on excised tissue to detect and localize the oncoproteins expressed by these tumors (mentioned in the preceding paragraph) are valuable for their characterization.

Germinoma

Germinomas are usually solid tumors that may contain cystic foci. The most common germ cell tumor is a pure germinoma, composed of sheets or lobules of uniform cells with large nuclei and clear cytoplasm that exhibit immunohistochemical labeling for PLAP on their cell membrane surfaces.²⁸⁴ Mitoses are common, but intratumoral hemorrhage and necrosis are uncommon. These tumors are not encapsulated, and they tend to grow by invasion of neighboring structures. In the pineal region, they surround and engulf the pineal calcifications and may

invade the adjacent thalami and quadrigeminal plates.^{109, 305} In the suprasellar region, these tumors appear as rounded or lobulated masses in the floor of the third ventricle, compressing and invading the optic chiasm and surrounding the pituitary stalk¹⁹; they may also extend superiorly, infiltrating the walls of the third ventricle. Seeding of tumor cells may occur into the CSF with both ependymal and subarachnoid spread of tumor.

More than 90% of pineal region germinomas occur in males, whereas for tumors in the suprasellar region, the sex distribution is approximately equal.^{19, 360}

Pure germinomas are highly radiosensitive, and 5 year survival rates of 65% to 95% are reported.²⁸⁴ Adjuvant chemotherapy may permit reduction in radiation dosage with comparable survival rates. Extent of disease at the time of diagnosis is an important prognostic factor.¹⁵²

On both CT and MRI, germinomas in the pineal and suprasellar regions appear as well circumscribed and mostly homogeneous rounded or lobulated masses.^{19, 109, 305, 360} Their hypercellularity explains their notable hyperdensity on CT (Fig. 5-49A) and their isointensity to gray matter and hypointensity relative to CSF on T2-weighted MR images (Fig. 5-50A, B). Intratumoral cysts are occasionally found and are easily distinguished from the surrounding solid tumor. Intratumoral hemorrhage and necrosis are rare occurrences. CT visualization of intratumoral calcification in a cluster likely signifies engulfment or displacement of the normal calcified pineal gland; widely dispersed calcifications favor a diagnosis of a primary pineal cell neoplasm.²⁸⁴ The solid parts of these tumors exhibit uniform contrast enhancement, and spread of tumor from the pineal region into the quadrigeminal plate or

Figure 5-49. Germinoma of the pineal region. *A*, Axial CT image demonstrates a well circumscribed round hyperdense mass in the pineal region extending slightly to the left and indenting the posteromedial aspect of the left thalamus (arrow) with a thin hypodense rim (likely representing edema) at the interface with the left thalamus. *B*, Following intravenous contrast administration, the mass demonstrates diffuse contrast enhancement (arrow).

thalami or from the floor of the third ventricle into the optic chiasm and pituitary stalk can be clearly delineated on either CT or MRI images after IV administration of contrast medium (Figs. 5-49B and 5-50C).^{19, 241} Differentiation of suprasellar germinoma from JPA on either CT or MRI may be difficult, but clinical differences in age and presenting symptoms usually permit accurate characterization.¹⁹

Teratoma

Teratomas are the second most common germ cell tumors. They originate from multipotential germ cells that recapitulate normal somatic development by developing

elements of the three embryonic germ layers—ectoderm, endoderm, and mesoderm.²⁸⁴ They are subdivided pathologically into mature and immature teratomas. *Mature teratomas* are composed entirely of fully differentiated tissue elements that may be arranged in patterns simulating those of normal organogenesis and originating from ectoderm (skin, brain, choroid), mesoderm (bone, tooth, cartilage, fat, muscle), and endoderm (intestine, respiratory).²⁸⁴ *Immature teratomas* occur more commonly,²⁰⁰ demonstrate greater hypercellularity and mitotic activity, and are composed of incompletely differentiated tissue elements resembling fetal tissues (e.g., the developing neural tube).²⁸⁴ An occasional teratoma contains a malignant component, such as rhabdomyosarcoma, undifferentiated sarcoma, squamous cell carcinoma, or adenocarcinoma.²⁸⁴

Figure 5-50. Germinoma of the suprasellar region. *A*, Sagittal T1-weighted MR image demonstrates a bulky lobulated ill defined isointense (with gray matter) tumor that nearly completely fills the third ventricle and extends downward into the sella (arrow) and posteriorly into the preoptine cistern. The belly of the pons is flattened and displaced posteriorly by this extensive tumor. *B*, Axial T2-weighted image through the level of the sella. The homogeneously isointense intrasellar tumor (arrow) extends bilaterally to encase the adjacent internal carotid arteries and posteriorly into the preoptine cistern, abutting the ventral surface of the pons on the right. *C*, Following intravenous administration of gadolinium, a sagittal T1-weighted image demonstrates patchy contrast enhancement of this extensive tumor (arrow).

Teratomas occur almost exclusively in males in the pineal, parapineal, and suprasellar regions. The clinical presentation for these lesions is earlier than for germinomas, usually during the first decade of life.^{10, 144, 200} On gross inspection, teratomas are typically well defined lobulated masses containing multiple structures, including mucus-filled cysts, nodules of cartilage and bone, and, rarely, teeth and hair.²⁸⁴ In the pineal region, these tumors are not usually invasive.¹⁹ For mature teratomas that can be completely excised, the 5-year survival rate is 80% to 90%.²⁰⁰

On both CT and MRI, teratomas are characterized by their striking heterogeneity in density and signal.^{10, 19, 109, 241, 305, 360} Intratumoral cysts with well-defined margins and variable density or signal of contents (watery, proteinaceous, lipid) are intermixed with calcifications or ossifications and areas of variegated soft tissue appearance, including hemorrhage. Dilatation of the lateral and third ventricles may indicate compression of the cerebral aqueduct by the tumor mass. Contrast enhancement is variable and, when patchy or ringlike, raises the possibility of malignant degeneration (Fig. 5–51).¹⁹ Invasion of neighboring structures can best be assessed on postcontrast images.

Other Germ Cell Tumors

Endodermal sinus (yolk sac) tumor is characterized by the accumulation of a myxoid matrix within a meshwork of primitive epithelial cells. *Embryonal carcinoma* is composed of large primitive cells that form abortive papillae and may attempt to replicate the structure of the early embryo. *Choriocarcinoma* consists of very large multinucleated trophoblastic cells that attempt to simulate placental tissue and include ectatic vascular channels that are prone to hemorrhage. Elements of these tumors may be found in germinomas or teratomas, and such tumors are then classified as mixed germ cell tumors.^{102, 284} Approximately 10% of germ cell tumors contain more than one cell type.^{19, 102}

All of these neoplasms, including the mixed germ cell tumors, have a high mitotic rate and a worse prognosis than pure germinomas or teratomas.^{152, 212, 284} These lesions exhibit a strong propensity for seeding via the CSF, for hematogenous metastasis to lung and bone, and even for spread of tumor via a ventriculoperitoneal shunt catheter into the peritoneal cavity.

Differentiation of these lesions on CT or MRI studies from pure germinoma or teratoma depends on demonstration of a pineal region or suprasellar region mass with areas of intratumoral necrosis and hemorrhage. Hemorrhage is particularly common in choriocarcinoma, reflecting the vascular stroma of that tumor. However, these findings are nonspecific, and individual tumor type is best established with immunohistochemical evaluation of excised tumor tissue.^{19, 241, 284, 305}

Tumors of the Sellar Region

Tumors of the pituitary gland and adjacent structures reflect the variety of tissues involved in the formation of these structures. Intraseilar, suprasellar, and parasellar tu-

mors affect the CNS by expansion, with resultant compression of cranial nerves and the base of the brain, or by interference with the hypothalamic-neurohypophyseal pathway. Alternatively, certain neoplasms, mainly intraseilar, may become clinically manifest because of endocrine hyperfunction.

The most common neoplasms in this region are pituitary adenomas and craniopharyngiomas, both of which are considered to arise from derivatives of Rathke's pouch, the embryonic infolding of endoderm that extends superiorly from the stomodeum and gives rise in early fetal development to the adenohypophysis (anterior lobe of the pituitary gland). The anterior lobe constitutes 75% of the volume of the pituitary gland.²³⁷ The posterior lobe of the pituitary gland is of neuroectodermal origin, extending inferiorly from the hypothalamus through the pituitary stalk (infundibulum). Neoplasms arising in the posterior pituitary are extremely rare.

Less common masses in the sellar region, all of nonhypophyseal origin, are chordomas, meningiomas, gliomas of the optic pathways, germinomas, teratomas, and metastases.

Pituitary Adenoma

Adenomas of the anterior pituitary are relatively common benign neoplasms, representing 10% to 15% of all intracranial tumors.¹⁷¹ They are mainly tumors of adulthood, with less than 3% occurring in individuals younger than 18 years.²³⁷ Pituitary adenomas vary greatly in size, but the vast majority are less than 10 mm in diameter and are designated by convention as *microadenomas*. In a series of 1000 unselected autopsy specimens, 3.1% of pituitary glands contained microadenomas, all from individuals older than 40 years.²³⁷

Microadenoma

Microadenomas are typically well demarcated lesions. Although they lack a definite capsule, they can be distinguished on gross inspection from the normal pituitary gland because they have a pseudocapsule of compressed pituitary tissue.²⁰¹ Approximately 75% of pituitary adenomas are hormonally active; compared with nonfunctional (endocrinologically inactive) adenomas, hormonally active adenomas usually present earlier in their course of evolution when they are much smaller, with symptoms and signs of endocrine hyperfunction.²⁰¹ They are generally classified on the basis of the hormone produced—for example, lactotroph (prolactin), somatotroph (growth hormone), corticotroph (ACTH), thyrotroph (TSH), and gonadotroph (FSH).¹⁷¹ Cells that secrete prolactin and growth hormone and the tumors arising from them tend to be located in the lateral portions of the gland, whereas cells that secrete ACTH, TSH, and FSH and the tumors arising from them tend to be located centrally.^{171, 201, 237}

Approximately 50% of hormonally active adenomas are prolactinomas.²⁰¹ They arise mainly in women (female-to-male ratio, 4–5:1), who typically present in young adulthood with amenorrhea, galactorrhea, and infertility.²³⁷ Loss of libido and impotence are the most common presenting symptoms in males. The symptoms and signs are less

Figure 5-51. Teratoma in the suprasellar region. *A*, On this axial noncontrast CT image, an ovoid well circumscribed heterogeneous mass containing several cystic areas (arrow) fills the suprasellar cistern. *B*, Axial T1-weighted MR image displays a heterogeneously hypointense (to gray matter) suprasellar tumor with several small and large intratumoral cysts (arrow). *C*, Sagittal T1-weighted image following intravenous gadolinium demonstrates a multicystic suprasellar mass (arrow) that elevates and posteriorly displaces the floor of the third ventricle. The solid elements of this tumor demonstrate diffuse contrast enhancement, giving it a honeycomb-like appearance.

pronounced in postmenopausal women and in men, in whom the tumors may manifest clinically only when they have become large enough to compress the visual pathways or cause pituitary hypofunction.²⁰¹ The great majority of prolactin-secreting tumors lie in the lateral aspect of the anterior pituitary.

Elevation of the serum prolactin concentration above the normal upper limit of 20 ng/mL raises the level of

suspicion for the presence of prolactinoma, but elevated serum prolactin values can also be associated with ingestion of certain drugs (notably the phenothiazines and the tricyclic antidepressants), the presence of a suprasellar mass compressing the hypothalamus or pituitary stalk, and primary hypothyroidism.²⁰¹ Although markedly elevated serum prolactin values (>150 ng/mL) are almost always due to the presence of a prolactinoma, many patients with this

tumor present with prolactin values between 20 and 150 ng/mL; in this group, diagnostic imaging often provides evidence allowing differentiation of prolactinoma from nonneoplastic causes of hyperprolactinemia.

Somatotrophic and corticotrophic tumors each account for approximately 15% of microadenomas.⁹⁸ The former cause gigantism in children and acromegaly in adults and are usually located laterally within the pituitary gland. The latter are located centrally, cause Cushing's disease, and are typically very small. The great majority (75%) of patients presenting with Cushing's disease are female. Thyrotrophic and gonadotrophic tumors are relatively rare. About 10% of microadenomas secrete more than one hormone, most commonly prolactin and growth hormone.¹⁷¹

Approximately 25% of pituitary adenomas are nonfunctional, that is, they do not cause nor are they directly associated with endocrine hyperfunction.⁹⁸ These tumors are detected accidentally as microadenomas when patients undergo diagnostic imaging for other clinical indications, are discovered incidentally at autopsy, or present clinically at a later stage as macroadenomas when they are large enough to compress the pituitary stalk, the optic chiasm, the cranial nerves in the cavernous sinus or suprasellar cistern, or the base of the brain.^{98, 201}

On CT and MRI, the pituitary gland is best visualized in the coronal plane. Because of the lack of bone artifact and the greater intrinsic soft tissue contrast on MRI, this modality has largely supplanted CT for the initial detection and localization of pituitary microadenoma. Approximately 80% to 85% of these tumors demonstrate focal subtle

hypointensity on T1-weighted images and focal mild hyperintensity on T2-weighted images. However, the differential signal intensity between the tumor and surrounding normal pituitary tissue is often very slight (Fig. 5-52A), thus explaining the 15% to 20% false-negative rate for MRI evaluation.¹⁷⁴

Intratumoral calcification occurs only rarely in pituitary adenomas and even more rarely in the microadenomas.²³⁷ Intratumoral necrosis, cyst formation, and hemorrhage are also infrequent occurrences that are much more likely to be found in the larger tumors. These changes typically cause heterogeneity of the density or signal pattern within the lesion.

The use of thin section T1-weighted images obtained after IV bolus administration of gadolinium improves the sensitivity and specificity of MRI for the detection and localization of pituitary microadenomas.²³⁵ The normal pituitary gland lacks a blood-brain barrier and thus opacifies rapidly and homogeneously after IV administration of contrast medium. The uptake of contrast agent by microadenomas is slower than that of the gland, and this difference provides greater conspicuity of the relatively hypointense tumor over the first 1 to 2 minutes after injection (Fig. 5-52B). Rapid sequence coronal single slice T1-weighted imaging of the sella immediately after IV bolus administration of gadolinium with images obtained consecutively at 10 second intervals provides a "dynamic" demonstration of the difference in contrast uptake between tumor and normal pituitary (Fig. 5-53).²⁰¹ A similar result can be obtained on CT with the use of thin-section coronal scans

Figure 5-52. Prolactin secreting pituitary microadenoma. A, Coronal T1-weighted thin section MR image through the midsella demonstrates a round isointense mass arising from the right side of the pituitary gland and projecting upward into the suprasellar cistern (arrow). B, Coronal T1-weighted image obtained shortly following intravenous gadolinium administration. Normal pituitary tissue demonstrates homogeneous contrast enhancement, while the round mass shows little or no enhancement.

Figure 5-53. Pituitary microadenoma. Coronal T1-weighted MR image obtained during a dynamic scanning sequence following bolus intravenous administration of gadolinium. A 5 mm in diameter ovoid hypointense lesion in the left inferior aspect of the pituitary gland (arrow) fails to take up the contrast medium as rapidly as the surrounding normal pituitary tissue.

obtained after IV bolus administration of iodinated contrast medium; on early rapid sequence serial images, the microadenoma appears hypodense relative to the homogeneously contrast enhancing normal pituitary tissue. This difference in contrast enhancement effect fades after several minutes, and later or delayed images may mask the presence of the tumor or rarely may demonstrate reversal of the image contrast pattern, with the adenoma enhancing more strongly than the surrounding tissue.²⁰¹

Laterally placed microadenomas may cause either unilateral upwardly convex bulging of the overlying superior margin of the pituitary gland into the suprasellar cistern or downward protrusion of the inferior margin into the floor of the sella, or both. Also, the pituitary stalk may be displaced contralaterally by the expanding microadenoma. However, these findings are inconsistent, depending on the size of the tumor and the location of its epicenter; when present, they may raise the level of confidence in the diagnosis of microadenoma, but their absence does not detract from the significance of an intrasellar hypodense or hypointense mass. Also, pituitary stalk deviation can be seen in individuals without symptoms, signs, or imaging evidence of intrasellar or suprasellar tumor.²

The differential diagnosis of pituitary microadenoma on MRI or CT is limited. Pituitary adenomas may contain cells that are undergoing mitosis or may demonstrate dural invasion without being classified as malignant. The diagnosis of primary pituitary carcinoma is made only rarely and then usually in the circumstance of distant metastasis.³³⁰ Most malignancies occurring within the gland are metastases from primary carcinomas of the breast, lung, kidney, and gastrointestinal tract,^{156, 330} although metastases account for only about 1% of intrasellar and parasellar tumors.²³⁷ Often multiple and tiny, metastases are demonstrated only on postcontrast high resolution images.

Nonneoplastic inflammatory entities that may involve the anterior lobe of the pituitary gland include lymphocytic hypophysitis and sarcoidosis. Lymphocytic hypophysitis is a rare disorder, likely autoimmune, that occurs mainly in young women during late pregnancy or postpartum. It is characterized by diffuse lymphocytic infiltration of the anterior pituitary. On imaging studies, the pituitary gland appears diffusely enlarged and demonstrates contrast enhancement.¹⁹² Sarcoidosis, another autoimmune disorder, affects the CNS in about 5% of cases, notably involving the meninges and parenchymal structures at the base of the brain. On imaging studies, multiple foci of ill-defined contrast enhancement are seen within and enveloping the surfaces of the hypothalamus, optic chiasm, and pituitary stalk (Fig. 5-54).⁷²

Intrapituitary focal abnormalities are commonly identified on MRI of asymptomatic volunteers¹³⁰ and as incidental findings in large autopsy series.¹⁷¹ These include not only microadenomas but also Rathke's cleft cysts (see Fig. 5-59) (see later) and other benign cysts of uncertain origin. The incidence of such cysts on autopsy series varies from 5.8% to 8.3% of individuals older than 30 years.¹⁷¹ In one double-blinded series of asymptomatic adult volunteers, MRI demonstrated intrapituitary focal hypointensities on T1-weighted imaging that were consistent with microadenoma or benign pituitary cyst in 15% of subjects.¹³⁰ Another possible explanation proposed for these "incidentalomas" is magnetic susceptibility induction of signal distortion in the floor of the sella near the junction with

Figure 5-54. Sarcoidosis involving the base of the brain. Axial postgadolinium T1-weighted MR image demonstrates patchy diffuse contrast enhancement of the leptomeninges enveloping the base of the brain. A large focus (arrow) involves the pituitary stalk.

the sphenoid sinus.²⁰¹ Most of these lesions, apparent or real, are very small (<3 mm) and, in the absence of correlating clinical symptoms or signs, can be followed with periodic monitoring on an annual or biannual basis.²⁰¹

Macroadenoma

When an adenoma of the pituitary gland reaches or exceeds 10 mm in diameter, it is designated by convention a *macroadenoma*. The great majority of such lesions are endocrinologically nonfunctional, although immunohistochemical and electron microscopic studies now suggest that these “null cell” tumors may be elaborating proteins that are involved in the formation or control of hormones.³²⁹ The tumors often become clinically evident in middle age, when they reach sufficient size to compress the optic chiasm, causing a disturbance in vision, typically an asymmetric bitemporal hemianopsia. Detailed clinical and laboratory evaluation may reveal evidence of hypopituitarism due to compression of the normal pituitary gland or stalk, but this is rarely a presenting symptom.³³⁰

Macroadenomas originate as intrasellar masses that slowly expand in all directions, notably upward out of the sella, protruding into the suprasellar cistern and eventually

elevating and compressing the optic chiasm, the hypothalamus, and the floor of the third ventricle (Fig. 5–55B, C). They also spread laterally and can invade across dura into the cavernous sinus and partially or completely encase the internal carotid artery.²⁰¹ Slow tumor growth in the inferior direction leads to thinning and erosion of the floor of the sella with protrusion into the underlying sphenoid sinus. On plain films and CT images this chronic slow enlargement causes expansion of the sellar cavity with thinning of the bony cortex of the dorsum, floor, and anterior wall of the sella.

Histologically, pituitary adenomas consist of small oval or polyhedral cells in a sheetlike monomorphous array, which contrasts markedly with the pleomorphic acinar pattern of the normal anterior pituitary gland.³²⁹ Cellular pleomorphism and even occasional mitoses may be seen in pituitary adenomas but do not indicate aggressive biologic behavior.⁹⁷ Calcification in these tumors is rare (in the range of 1%)²³⁷ but may be more common in prolactin-secreting tumors.⁹⁷

Intratumoral necrosis, cystic change, and hemorrhage all occur more frequently in macroadenomas than in microadenomas.²⁰¹ Hemorrhage is present in 20% to 30% of macroadenomas; it may be associated with pituitary apoplexy, an

Figure 5–55. Pituitary macroadenoma with intratumoral hemorrhage and cystic changes. A, Axial noncontrast CT image demonstrates a soft tissue mass filling the suprasellar cistern. The tumor is mainly isodense with adjacent brain, but a faintly hyperdense focus at the right lateral margin (arrow) suggests recent hemorrhage. On a sagittal T1-weighted MR image (B), the tumor is seen to enlarge the sella and extend into the suprasellar cistern, elevating and slightly posteriorly displacing the optic chiasm and the anterior floor of the third ventricle. It is mainly homogeneously isointense with adjacent brain, but contains several hyperintense foci (the largest is located in the posterior portion of the tumor and is indicated by an arrow) which likely represent subacute hemorrhage.

Illustration continued on opposite page

Figure 5-55. *Continued.* C, Coronal T2-weighted image at a level through the anterior third ventricle. The dome of the tumor contains a large cyst. The mass displaces the supraclinoid internal carotid arteries laterally (arrow) and elevates and flattens the floor of the third ventricle. Sagittal (D) and coronal (E) T1-weighted images following intravenous gadolinium demonstrate homogeneous contrast enhancement of the solid portions of this large tumor. The arrow in D delineates the large focus of subacute hemorrhage in the posterior aspect of the tumor. The arrow in E demonstrates elevation and stretching of the proximal (A1) segment of the left anterior cerebral artery by this large intra- and suprasellar mass.

acute clinical event characterized by sudden onset of severe headache, visual loss, and hypotension. More often, however, intratumoral hemorrhage is subclinical and discovered incidentally on MRI (Figs. 5-55B and 5-56A).^{201, 243} Hemorrhage occurs even more commonly in patients with prolactinomas who are being treated with bromocriptine.³⁵⁷

On CT, macroadenomas often appear as large, homogeneously isodense, rounded midline masses arising out of the sella and insinuating upward to elevate and compress the optic chiasm and overlying third ventricle (Fig. 5-55A).²³⁷ On occasion, a tumor may grow so large as to invaginate the floor and walls of the third ventricle and obstruct the foramen of Monro. Areas of intratumoral necrosis or cystic degeneration appear as hypodensities within the tumor mass, whereas acute or subacute hemorrhage causes focal intratumoral hyperdensity.

Because MRI offers multiplanar imaging capabilities and is not degraded by beam hardening artifacts due to adjacent bone, it is the preferred modality for visualizing the pituitary gland. Pituitary macroadenomas appear hypo-

intense relative to gray matter on T1-weighted images and hyperintense on T2-weighted images (Figs. 5-55B, C and 5-56A).²³⁷ The T2 hyperintensity appears to correlate with softening of the tumor observed at the time of surgical removal and may reflect intratumoral necrosis.^{201, 308} Normal pituitary tissue is usually severely compressed downward into the sellar floor by these bulky tumors and cannot be recognized.²⁰¹

After IV administration of a contrast agent, delayed moderate contrast enhancement of the solid portions of the tumor mass appears on both CT and MRI (Figs. 5-55D, E and 5-56B).^{174, 201, 235, 237} A major advantage of MRI is the ability to demonstrate the location and status of the internal carotid arteries relative to the tumor. Lateral tumor extension into the cavernous sinus may displace the carotid flow void laterally (Figs. 5-55C and 5-56). Further tumor extension may surround the flow void, indicating the presence of vessel encasement.⁶⁸ In contradistinction to meningioma, such encasement by macroadenoma rarely causes arterial constriction or occlusion.

Figure 5-56. Pituitary macroadenoma with intratumoral hemorrhage. *A*, Coronal T1-weighted MR image demonstrates a very large multilobulated well circumscribed homogeneously hypointense tumor widening the sella and extending superiorly and bilaterally, more to the right than to the left. The most superolateral extension of this mass contains a large focal hyperintensity representing late subacute hemorrhage (arrow). The pituitary stalk is deviated to the left of the midline by the predominantly right sided tumor. Note that the supraclinoid internal carotid arteries on both sides are compressed and displaced far laterally, as are the medial aspects of both temporal lobes. *B*, Following intravenous administration of gadolinium, an axial T1-weighted image demonstrates diffuse homogeneous contrast enhancement of this multilobulated tumor (arrow).

Craniopharyngioma

Craniopharyngiomas are benign, partly cystic, epithelial tumors that occur almost exclusively in the sellar region and are presumed to arise from remnants of Rathke's pouch epithelium.¹⁵⁰ They represent 1.2% to 4.6% of all intracranial tumors but are more common in children, in whom they represent 5% to 10% of intracranial neoplasms.⁴³ They are most frequently suprasellar in location with an intrasellar component; less commonly (about 20% of cases), they may be entirely suprasellar, and approximately 5% are purely intrasellar.^{133, 150}

These tumors have a bimodal age distribution that largely corresponds to two clinicopathologic forms, adamantinomatous and papillary.¹⁵⁰ Approximately two thirds of cases of craniopharyngioma occur in the first two decades of life, mainly between ages 5 and 14 years; the great majority of these are of the adamantinomatous variety.^{150, 202, 369} The second age peak is in middle age (40 to 50 years); almost all papillary craniopharyngiomas occur in this group.^{76, 150} Craniopharyngioma has no sex predilection.

Craniopharyngiomas are slow growing tumors that extend superiorly and often insinuate into the third ventricle. They may also expand anteriorly under the frontal lobes (30%), posteriorly into the interpeduncular cistern with impingement on and posterior displacement of the ventral margins of the midbrain and upper pons (20%), and laterally into the medial aspect of the middle cranial fossa (20%).^{133, 150} The adamantinomatous tumors provoke an intense gliosis in the adjacent brain and become firmly adherent to adjacent brain and vessels. On gross inspection, they have a multilobulated inner aspect with nodules of solid tissue separated by cysts of varying size.¹⁵⁰ The cystic component is usually predominant in the adamantinoma-

tous tumors and much less prominent in the papillary variety.²⁰¹ The papillary tumors often involve the third ventricle.¹⁵⁰

Calcification is present in the solid portions of nearly 90% of adamantinomatous craniopharyngiomas but is much less common in the papillary tumors.^{201, 291, 369} The cyst contents have a "machine oil" color and consistency and frequently contain suspended debris with a high cholesterol content.¹⁵⁰ Microscopically, the adamantinomatous tumors consist of broad strands and cords of stratified squamous epithelium with nodules of keratin and dystrophic calcification.¹⁵⁰ In the papillary tumors, sheets of squamous epithelium form papillae with a fibrovascular stroma, but keratin, cholesterol deposits, and calcification are typically lacking.^{76, 150}

Like pituitary macroadenomas, these slow growing tumors present clinically most commonly with visual disturbances secondary to compression of the optic chiasm, nerves, or tracts.^{150, 201, 369} Endocrine deficiencies are slightly less frequent. Compression of the neurohypophysis leads to diabetes insipidus in up to 15% of children and up to 30% of adults.¹⁵⁰ Symptoms and signs of increased intracranial pressure (headache, nausea, vomiting, papilledema) secondary to third ventricular obstruction are also common presenting findings that may lead to cognitive impairment and personality changes.^{150, 201}

On CT, these tumors typically appear as heterogeneously hypodense suprasellar masses with nodular solid areas intermixed with cystic areas of varying size. The cyst contents are more dense than CSF. More than 80% of craniopharyngiomas in children (usually of the adamantinomatous variety) demonstrate nodular and curvilinear calcifications in the solid nodules and in the cyst walls (Fig. 5-57A).^{133, 238, 369} Papillary craniopharyngiomas in adults appear more solid and rarely demonstrate calcification.⁷⁶

Figure 5-57. Craniopharyngioma in a child. *A*, Axial postcontrast CT image of a large suprasellar cyst with several nodular calcifications of varying size (*arrow*) in the wall of the cyst. *B*, Axial T2-weighted MR image demonstrates strongly hyperintense homogeneous cyst contents. The well circumscribed cyst (*arrow*) displaces the anterior cerebral arteries anteriorly and the middle cerebral arteries bilaterally. *C*, Coronal T1-weighted post-gadolinium image demonstrates a cystic intra-/suprasellar mass with strong contrast enhancement of the cyst wall (*arrow*). The cyst contents are isointense with gray matter, reflecting their high protein content.

Cysts are found in approximately 50% of papillary tumors versus about 90% of adamantinomatous neoplasms.²⁹¹ In contrast to pituitary adenomas, slow growing craniopharyngiomas do not usually enlarge the sella but rather gradually erode the posterior clinoid processes and the upper portion of the dorsum sellae.

The adamantinomatous suprasellar tumors appear as heterogeneous masses of variable intensity on T1-weighted MR images.²⁰¹ Areas containing calcification usually appear more hypointense. The cystic components are well margined and vary in signal but are commonly hyperintense relative to gray matter, reflecting high concentration

of protein in the cyst contents (Figs. 5-57C and 5-58B, C).²⁹¹ On T2-weighted images, the solid areas vary from hypointense to mildly hyperintense as compared with gray matter, whereas the cysts present a more internally uniform, hyperintense appearance (Figs. 5-57B and 5-58A).²⁰¹ The papillary tumors have a more uniform and homogeneous appearance.^{201, 237, 291}

On both CT and MRI, after IV administration of contrast agents, enhancement of the noncalcified solid components of the adamantinomatous tumors and of the solid papillary tumors is typically intense and uniform (Figs. 5-57C and 5-58B, C).^{76, 133, 203, 237, 291, 369}

Figure 5-58. Craniopharyngioma in an adult. A, Axial T2-weighted MR image demonstrates a multilobulated multicystic hyperintense midline tumor (arrow) with irregular margins that has insinuated itself between the basal ganglia of the two cerebral hemispheres. The tumor extends more to the right than to the left of the midline, and the right globus pallidus is compressed and displaced laterally. The cyst contents are more hyperintense than the solid tumor rim in this papillary tumor. Axial (B) and right parasagittal (C) T1-weighted images following intravenous gadolinium demonstrate contrast enhancement of the solid tumor rim (arrow). The cyst contents are hyperintense relative to cerebrospinal fluid, reflecting their high protein content. On the sagittal image, note that this cystic tumor extends into and nearly obliterates the third ventricle with its superior margin projecting into the floor of the right lateral ventricle; posteroinferiorly, the tumor projects into the interpeduncular cistern and displaces the midbrain posteriorly.

Both adamantinomatous and papillary craniopharyngiomas are managed surgically. Ten-year recurrence free survival rates vary from 64% to 96%.^{76, 150} The extent of surgical resection is the most important factor in predicting recurrence; because of the intense gliotic reaction provoked by the tumor as it impinges on adjacent brain and the adhesion of large tumors to vascular structures in the suprasellar region, incomplete surgical resection remains a significant problem, especially in tumors larger than 5 cm in diameter.¹⁵⁰

Rathke Cleft Cyst

Both Rathke cleft cysts and craniopharyngiomas are considered to arise from embryonic rests of Rathke's pouch.²⁹⁰ In normal embryonic development, Rathke's pouch regresses by the sixth week of gestation into a narrow cleft. Persistence and enlargement of that cleft is believed to be the cause of Rathke cleft cysts, which are lined by cuboidal or columnar epithelium and are usually located in the pars intermedia between the anterior lobe (adenohypophysis) and posterior lobe (neurohypophysis) of the pituitary gland.⁹⁷

Rathke cleft cysts are typically small (2 to 10 mm), thin-walled, smoothly margined intrapituitary cysts with mucinous contents.⁹⁷ Less commonly, the contents may be serous.⁷⁴ They are usually asymptomatic and found incidentally on MRI or at autopsy. In an unselected series of 1000 cases, incidental Rathke cleft cysts were found in

11.3%.³²⁷ Nearly 90% occur in the center of the pituitary gland.³²⁷ Larger cysts may be both intrasellar and suprasellar and may become symptomatic if they compress the pituitary gland, pituitary stalk, or optic chiasm, but such compression is unusual. They are found in patients in all age groups but are usually identified in adults. A 2:1 to 3:1 female predominance has been reported,²⁸⁵ but this figure may reflect selection bias, because more women than men undergo pituitary imaging, mainly for menstrual problems, hyperprolactinemia, and infertility.

On CT, 75% of Rathke cleft cysts appear as round, well-marginated, hypodense intrapituitary lesions.²⁸⁵ The density of the cyst likely reflects the concentration of mucoprotein in the cyst contents. Calcification is not found in these cysts.^{201, 237} On MRI also, they appear discrete and sharply margined. On T1-weighted images, approximately two thirds of Rathke cleft cysts appear hyperintense and one third hypointense relative to gray matter (Fig. 5-59B)²⁸⁵; this variance is also likely related to the protein content of the cyst fluid. On T2-weighted MR images, approximately 50% exhibit moderate to strong hyperintensity relative to gray matter (Fig. 5-59A), another 25% appear isointense, and a like number are hypointense.²⁸⁵ After IV administration of contrast agent, Rathke cleft cyst does not enhance on either CT or MRI, although the surrounding compressed pituitary tissue may exhibit rimlike enhancement.²³⁸

Tumors of the Neurohypophysis

Neoplasms arising in the posterior lobe of the pituitary gland or the pituitary stalk are very uncommon.

Figure 5-59. Rathke cleft cyst. Axial T2-weighted (A) and coronal postgadolinium T1-weighted (B) images demonstrate a small smoothly margined cystic mass (arrows) within and projecting above the pituitary gland. The cyst appears slightly hyperintense relative to gray matter on both T1-weighting (B) and T2-weighting (A). There is no contrast enhancement of its contents or margins.

Granular cell tumor of the neurohypophysis (also known as choristoma or pituicytoma) is a rarely occurring, benign, slow growing intrasellar or suprasellar mass that originates within the posterior pituitary or the pituitary stalk and presents as a well defined rounded mass composed of densely packed nests of large cells with a granular cytoplasm.³⁴³ These tumors, considered to be of neural crest or glial origin, exhibit intense immunoreactivity for the S-100 tumor marker.¹²⁴ Like many intrasellar and suprasellar neoplasms, granular cell tumors usually develop insidiously and present with hormonal and visual disturbances secondary to compression of normal pituitary and optic pathway structures. On imaging studies, they appear as well circumscribed round masses within the posterior pituitary or on the posterior aspect of the pituitary stalk. The tumors are isodense with brain on CT and isointense with gray matter on T1- and T2-weighted MR images.^{69, 201, 237} The posterior pituitary "bright spot" on T1-weighted images is effaced or absent.³⁴³ Granular cell tumors are described as richly vascular and demonstrate strong contrast enhancement.^{238, 343}

Langerhans cell histiocytosis involves the sellar region as a component of the Hand-Schüller-Christian syndrome; granulomas may be found in the pituitary stalk, hypothalamus, or both in association with destruction of the bony margins of the sella (see above). Imaging studies may demonstrate thickening and contrast enhancement of these structures (see Fig. 5-47).³³⁴

Chordoma

Chordomas are histologically benign neoplasms derived from remnants of the embryonic notochord. Despite their benign histology, they are locally invasive and destructive, behaving clinically like low grade malignancies.¹³² These tumors arise in or near the midline and occur most commonly at the proximal (clivus-basisphenoid) and distal (sacrum) ends of the notochord. Approximately 40% of chordomas arise in the basisphenoid region.⁷⁰ They are uncommon tumors, representing less than 0.2% of all intracranial neoplasms.¹³² Chordomas can present clinically in any age group, but their peak incidence is in patients between 20 and 50 years, and less than 5% are identified in children.^{70, 132}

Chordomas arising in the upper clivus expand slowly and inexorably in all directions, infiltrating and eroding the surrounding bone. Posterior extension leads to the presence of a bulky lobulated mass in the prepontine cistern, compressing and displacing (but not invading) the pons and midbrain posteriorly. Anterior extension may manifest as a nasopharyngeal mass.^{77, 201} Upward growth causes destruction of the walls of the sella with extension of tumor into and above the sella. Tumor infiltration into the cavernous sinuses with encasement of arteries and nerves is common. Sequestra of intratumoral necrotic bone and calcification and foci of intratumoral hemorrhage are common findings.^{77, 132, 201} Histologically, chordoma consists of clusters of large vacuolated physaliferous (Greek for "bubble-bearing") cells interspersed with abundant extracellular mucinous material and separated into lobules by fibrous septa.^{70, 132}

The clinical presentation of this slowly expanding neoplasm is insidious and depends on its precise location. The majority of patients present with head or neck pain and cranial nerve deficits.¹³² The most common presenting complaint is diplopia, noted in 60% to 90% of cases.¹⁰⁷ Upward extension of chordoma causes visual disturbances and hypopituitarism, whereas posterior extension leads to extraocular nerve palsies.²⁰¹ Hearing loss and dysphagia are relatively common presenting findings that correlate with downward and anterior spread of tumor.

CT of clival chordoma demonstrates irregularly marginated erosion and destruction of the bony clivus with heterogeneous attenuation of the associated intraosseous and extraosseous lobulated soft tissue mass.¹³² The heterogeneity is due to the presence of hyperdense intratumoral bony sequestra and calcifications intermixed with areas of hypodensity and hyperdensity secondary to cystlike mucinous collections as well as intratumoral hemorrhage.⁷⁷ On T1-weighted MR images, the infiltrating tumor appears isointense with gray matter in 75% of patients and mildly hypointense in the remaining 25% (Fig. 5-60A, C). In either case, the tumor presents a striking contrast to the diffusely hyperintense T1 signal of the adjacent normal marrow fat of the clivus.^{201, 319} On T2-weighted images, chordoma demonstrates moderate heterogeneity of signal with areas of hyperintensity intermixed with linear strands of hypointensity (Fig. 5-60B).^{201, 216, 319} After IV administration of contrast material, varying and heterogeneous contrast enhancement is seen within the tumor mass on both CT and MRI (Fig. 5-60C).⁹³

Differentiation of chordoma from *chondrosarcoma*, both on imaging and gross and microscopic examination, may be very difficult.^{77, 132} There is considerable overlap of both imaging and histological appearances between these two tumors. Tumor location may be of limited help in this differentiation; chordoma arises in or near the midline, whereas the majority of chondrosarcomas of the skull base tend to arise laterally in or near the petroclival junction. However, chondrosarcomas often spread medially into the clivus and posteriorly into the cerebellopontine angle, extending into the ipsilateral cavernous sinus and encasing the arteries of the circle of Willis in a manner similar to chordoma.⁹³ Immunohistochemical studies also aid in this differentiation; chordoma is of neural crest origin and stains positively for epithelial membrane antigen (EMA) and cytokeratin, but chondrosarcoma, being of mesodermal origin, does not take up these markers.²⁸³

Other neoplasms occurring in or metastasizing to the sellar region, including meningiomas, gliomas of the optic pathways, epidermoid tumors, germ cell tumors, and carcinomatous metastases, are considered elsewhere in this chapter.

Metastatic Tumors

Hematogenous metastases from extracranial primary malignant neoplasms may involve the skull, the dura, the leptomeninges, or the brain parenchyma. In adults, metastasis to the brain is most common.

Figure 5-60. Chordoma of the lower clivus and foramen magnum. Axial T1-weighted (A) and T2-weighted (B) MR images through the level of the lower clivus demonstrate a sharply margined lobulated mass in and to the right of the midline that is hypointense on T1-weighting and hyperintense on T2-weighting and has destroyed the lower clivus, infiltrating anteriorly into the longus colli muscles (arrow in B) and extending posteriorly into the premedullary cistern (arrow in A), displacing the medulla posteriorly and indenting its right ventrolateral margin. In (B), note that the tumor has encased the vertebral arteries bilaterally. C, Sagittal T1-weighted postgadolinium image demonstrates faint homogeneous contrast enhancement of this extensive tumor that presents anteriorly as a submucosal nasopharyngeal mass (arrow) and projects posteriorly to compress the medulla and upper cervical spinal cord against the posterior margin of the foramen magnum.

Metastases to the Brain

More than 30% of intracranial tumors detected in a multi-institutional prospective CT study were metastatic malignancies.¹⁶ Autopsy studies have demonstrated the presence of intracranial metastasis in approximately 25% of patients with cancer.²⁶⁶ The incidence of intracranial metastasis is rising because of (1) the wider availability and greater refinement of cross-sectional diagnostic imaging and (2) continuing improvements in other diagnostic and treatment modalities with resultant prolonged survival of patients with systemic tumors.^{230, 263}

The most common sources of intracranial metastasis, in order of decreasing frequency, are carcinomas of the lung and breast, malignant melanoma, and carcinomas of the kidney and gastrointestinal tract.^{10, 230, 268, 286} Certain primary malignancies, particularly bronchogenic carcinoma,^{52, 321, 324} carcinoma of the breast,^{231, 322} choriocarcinoma,²⁸⁶ and melanoma,^{41, 116} have a notable propensity to metastasize to the brain. Between 30% and 65% of patients with carcinoma of the lung exhibit cerebral metastases at autopsy, many of which were not clinically evident during life.^{154, 286, 321, 353}

The most common cause of death in patients with melanoma is metastasis to the brain; autopsy studies reveal cerebral metastases in up to 90% of patients with melanoma.⁴¹

Cerebral metastases occur most frequently at the junction of cortex and underlying white matter,²⁶⁸ a finding likely related to obstruction by circulating tumor cell emboli of the penetrating arteries, which abruptly narrow as they enter the subcortical white matter.^{87, 230, 286} Eighty percent of brain metastases are located in the arterial distribution zones of the cerebral hemispheres, with 3% in the basal ganglia and 15% in the cerebellum.²³⁰ A notable departure from this pattern occurs in the case of mucinous adenocarcinomas of gastrointestinal origin; although these tumors represent only 5% of intracranial metastases, approximately 50% occur in the posterior fossa, mainly in the cerebellum.⁸⁷ Metastasis to the cerebellum occurs mainly at the junction of the superior and inferior cerebellar artery distributions.²³⁰

Differentiation between solitary and multiple cerebral metastases has a major impact on the further management of the patient. The relative ratio of solitary-to-multifocal

cerebral metastases in autopsy series has been reported as approximately 50:50.²³⁰ However, experience with advances in diagnostic imaging, particularly with contrast enhanced MRI, suggests that about 70% of patients with cerebral metastasis demonstrate more than one lesion.^{10, 153, 238}

On gross inspection, small metastases are usually discrete, spherical, well circumscribed tumors (Fig. 5-61).²³⁰ However, microscopic examination often reveals tumor cell infiltration into the adjacent surrounding normal tissue with angioneogenesis, perivascular invasion, and reactive gliosis.^{230, 286} Histologically, metastases typically recapitulate the pattern of the tumor of origin.¹⁵³ These are markedly malignant neoplasms with high rates of mitotic activity.¹⁵³ Edema of the adjacent white matter is often disproportionately extensive in comparison with the small size of the tumor and may spread along white matter fiber tracts for a considerable distance.^{10, 230, 286, 321} As the tumor implant grows, it penetrates and distorts the surrounding gray and white matter. Further growth is typically associated with central necrosis like that seen in glioblastoma, leaving recognizable tumor tissue only at the periphery and around the blood vessels.²³⁰ Intratumoral hemorrhage is found in about 20% of cerebral metastases, notably in melanomas (Fig. 5-62), choriocarcinomas, and carcinomas of the lung, kidney, and thyroid.^{10, 205}

Although metastases to the CNS can occur in all age groups, more than 75% are found in older patients. The

age-specific incidence rises steeply after age 45 years.^{27, 256} Approximately 30% of patients with cerebral metastases are asymptomatic at the time of initial diagnosis—that is, the tumors are discovered incidentally during evaluation for other causes (e.g., head trauma) or are found on screening imaging surveys of patients who have primary tumors with a known high incidence of hematogenous seeding to the brain.²⁷ When symptoms occur, they are usually of insidious onset and slow progression and relate either to increased intracranial pressure or to localized mass effect; they include headache (in approximately 50%), nausea and vomiting, mental status or behavioral change, progressive neurologic deficit, and seizures. These symptoms do not differ from those caused by primary gliomas in the same area.²⁷

Mean survival time after pathologic confirmation of the diagnosis of cerebral metastasis is 1 to 3 months.³⁰ Despite advances in surgery, irradiation, and chemotherapy, the prognosis for patients with cerebral metastases from extracranial primary malignant neoplasms has only minimally improved, with survival in the range of 3 to 6 months.⁵⁸ When only a solitary parenchymal lesion of the brain can be identified and the extent of the disease in other organs is not progressing, surgical excision of the cerebral metastasis correlates with improvement in both quality and length of life.³¹³

The appearance of hematogenous cerebral metastasis on noncontrast CT scans corresponds closely to the gross pathologic changes already described. Small tumors appear as rounded homogeneously isodense or, less commonly, slightly hyperdense nodules relative to adjacent normal brain.^{5, 10, 52, 153, 268} The isodense lesions merge imperceptibly with the adjacent cortex and may be detected only when they distort the inner margin of the cortex. The hyperdense nodules typically represent small round cell tumors or other tumors with high nuclear-to-cytoplasmic ratios.¹⁵³ However, most metastases from melanoma and choriocarcinoma as well as some metastases from carcinomas of the thyroid and kidney appear hyperdense because of hemorrhage within the tumor (Fig. 5-62A). Some small lesions and virtually all large metastases have undergone central necrosis by the time they are detected and appear as ringlike masses with central lucency and a peripheral isodense or slightly hyperdense rim of irregular thickness.²⁶⁸ As already noted, edema (hypodensity) of the surrounding white matter is usually extensive and produces considerable mass effect (see Fig. 5-62). Calcification is rarely found in association with intracerebral metastases because of their rapid growth; however, it may occasionally be found in metastases originating from carcinoma of the breast or gastrointestinal tract.⁸⁷

Contrast enhancement is virtually universal in these tumors. Less than 4% of the metastases in a multiinstitutional prospective CT study did not demonstrate contrast enhancement of the viable peripheral tumor rim (in lesions with central necrosis) or of the entire tumor (in small solid lesions of homogeneous density).²⁶⁸ The enhancement is typically intense and fairly uniform within viable portions of the neoplasm, enabling clear separation of small tumor foci that are isodense on precontrast CT images from surrounding edema. The use of a double dose of iodinated contrast agent in combination with delayed image acquisi-

Figure 5-61. Hematogenous metastases of small cell carcinoma of the lung to the brain. Axial T1-weighted postgadolinium image demonstrates multiple contrast enhancing ring and ovoid lesions of varying size (arrows) at the junction of gray and white matter in both cerebral hemispheres. Although numerous, these tumors are relatively small and have not yet provoked grossly evident surrounding white matter edema.

Figure 5-62. Hematogenous metastases of melanoma to the brain with intratumoral hemorrhage. *A*, An axial noncontrast CT image demonstrates at least four foci of varying size located at gray/white junctions in both cerebral hemispheres. All four lesions contain blood/fluid levels (arrows) indicating the presence of intratumoral hemorrhage. The lesions in the frontoparietal regions bilaterally and the left deep frontal area have provoked considerable surrounding edema. *B*, An axial CT image at an adjacent level following intravenous contrast injection demonstrates faint ringlike contrast enhancement of the margins of several of these tumors (arrows).

tion increases the conspicuity of small tumor foci that might otherwise be overlooked and further improves both the sensitivity and the specificity of the examination.^{82, 294}

Definitive preoperative differentiation of metastasis from glioblastoma with CT is often not possible in an individual case, even though larger metastases generally retain a spherical or ovoid outline and extensive glioblastomas most commonly have much more irregular lobulated configurations and exhibit greater heterogeneity of density on contrast enhanced images. Definitive differentiation of multiple metastases from multiple pyogenic cerebral abscesses also is not usually possible with CT; although virtually all abscesses demonstrate uniformity and smoothness of contrast enhancing wall thickness, so may many small metastases. Extensive surrounding edema is also characteristic of both processes.

As noted previously, CT with contrast injection has been used for the preoperative screening evaluation of patients with carcinoma of the lung,⁵³ malignant melanoma,¹¹⁶ and choriocarcinoma who have no cerebral symptoms or neurologic deficit. In one study of individuals without clinical evidence of brain involvement, cerebral metastases were found on CT in 40% of patients with adenocarcinoma of the lung and 11% of patients with oat cell carcinoma of the lung³²⁴; in another study, 11% of patients with melanoma were found on CT to have metastatic intracranial lesions.¹¹⁶ Demonstration of unsuspected cerebral metastases in such patients may eliminate unnecessary surgery and permit earlier institution of more appropriate forms of treatment.

On evaluation with MRI, most intracerebral metastatic lesions have prolonged relaxation times (diminished signal on T1-weighted images and increased signal on T2-weighted images compared with normal brain).¹⁰ As with CT, differentiation of the lesion or lesions from surrounding white matter edema is often problematic on non-contrast images. Additionally, signal intensity of the tumor can be highly variable, depending on the tumor constituents; the signal characteristics in a given metastasis depend on the cellularity of the lesion, the extent of intratumoral necrosis, the presence and age of hemorrhage, the presence and extent of calcification, and the severity of surrounding edema.^{8-10, 153} Melanoma has a somewhat characteristic appearance if there has not been previous hemorrhage; the lesion is hyperintense on T1-weighted images and isointense with brain on T2-weighted images, most likely because of the free radical content of the melanin.^{8, 9} Metastases from mucinous adenocarcinomas of gastrointestinal origin often appear hypointense on T2-weighted images because of the high protein content of the mucin.¹⁰ If intratumoral hemorrhage has occurred, the signal pattern is determined by the nature of the blood degradation products, i.e., the age of the hemorrhage.^{9, 123}

Contrast enhanced MRI has proven even more sensitive than contrast enhanced CT for detection of intracranial metastatic disease.^{8, 140, 288} Multiplanar T1-weighted MR images obtained after IV administration of gadolinium, usually in a dose of 0.1 mmol per kg of body weight, are currently the most sensitive method for evaluation of intracranial metastatic disease.^{10, 238} As on CT, contrast

enhancement on MRI allows the reader to distinguish the gross margins of the metastasis from the surrounding edema (see Fig. 5–61), a differentiation not often permitted on precontrast T1- or T2-weighted MR images.

Several investigators have suggested that higher doses of gadolinium (0.2 to 0.3 mmol/kg) further improve the sensitivity of this examination for the detection of additional lesions, although (unlike CT) delayed MR images do not increase the contrast between the tumor and the surrounding brain.^{135, 359} In patients with known extracranial primary malignancy in whom standard dose contrast enhanced MRI of the brain appears to demonstrate a solitary parenchymal enhancing metastasis, it would seem appropriate and cost effective to repeat the postcontrast images with a higher dose of gadolinium, so as to more conclusively exclude the possibility of more metastases before surgical resection of the apparent solitary lesion is undertaken.

Metastases to the Skull and Intracranial Dura

Metastasis to the cranial vault or the base of the skull is associated with intracranial metastasis in 5% to 10% of cases.^{139, 286} Hematogenous metastasis to the calvarial diploë often leads to destruction of the internal and external tables and extension of tumor into the adjacent epidural space. In one autopsy series of patients with primary extracranial malignancy and intracranial metastasis, 18% demonstrated dural involvement (including epidural or subdural neoplasm) as the only site of intracranial metastasis.^{11, 266} Occasionally, dural metastasis may occur without an associated calvarial lesion, either as a nodular plaquelike focus or as a more extensive diffuse thickening of the dura.^{82, 230} Epidural or dural metastasis is most often secondary to carcinoma of the breast, lymphoma, carcinoma of the prostate, and neuroblastoma.²⁶⁶ Other common sources are carcinomas of the lung and kidney.¹¹ Although the dura is usually an effective barrier to further deep invasion, spread of tumor in the epidural space with nodular or bandlike soft tissue thickening is common. Symptoms usually relate to compression of the underlying brain parenchyma.¹¹

Irregularly margined focal osseous destruction of the bony calvaria or the skull base caused by metastasis to the diploë or marrow can be best defined on noncontrast CT scans obtained through the use of a bone targeting algorithm with wide window and high center settings.²³⁸ Destruction of the inner table of the skull allows extension of tumor into the intracranial epidural space, which can be demonstrated on CT scans obtained after IV administration of iodinated contrast medium with the use of a soft tissue algorithm and appropriate (“subdural window”) soft tissue window and center settings. These tumors typically demonstrate intense contrast enhancement, but recognition of the enhancing biconvex epidural tumor mass can be masked by the adjacent bone unless relatively wide window and high center settings are employed.

In current practice, early detection of small metastases in the diploë or in the dura can best be accomplished by utilizing T1-weighted MR images both before and after IV administration of gadolinium.¹¹ Small foci of intradiploic

Figure 5–63. Diffuse pachymeningeal and calvarial metastasis from carcinoma of the breast. Axial T1-weighted postgadolinium MR image demonstrates diffuse nodular and bandlike contrast enhanced thickening of the dura over the high right frontoparietal convexity. The process extends into the falx and across the midline into the high left frontal convexity dura. Several ovoid and plaquelike masses in the right frontoparietal convexity represent outcroppings of dural metastasis (arrow) and compress the underlying frontal and parietal lobes with resultant effacement of the sulci. Note the loss of normal fatty marrow signal in the diploë of the overlying right parietal bone, indicating the presence of calvarial tumor involvement. Immediately posterior and lateral to the arrow is a focal plaque of tumor extension into the subgaleal space, with elevation of the overlying subcutaneous fat of the scalp.

metastasis appear hypointense on noncontrast T1-weighted images and differ sharply from the adjacent hyperintense fatty marrow in the diploic space (Fig. 5–63). Postgadolinium T1-weighted images obtained with fat suppression typically demonstrate intense contrast enhancement of tumor in the epidural space or dura, which appears as nodular or curvilinear, bandlike thickening (see Fig 5–63); the underlying cerebral cortex is displaced inward, and (unlike leptomeningeal metastasis) the enhancing tumor does not extend into the cerebral sulci.³¹⁷ The findings may simulate those of meningioma, but epidural or dural metastasis typically appears hyperintense to adjacent cerebral cortex on T2-weighted images, whereas meningioma is nearly isointense with cortex on this pulsing sequence.^{11, 238, 317}

Leptomeningeal Metastasis (Leptomeningeal Carcinomatosis)

Hematogenous metastasis from primary extracranial malignant tumors may occur directly to the meninges, but

leptomeningeal carcinomatosis may also result from parenchymal neoplasm that breaches either the ependymal lining of the ventricles or the pia overlying the cortex, with seeding of tumor cells into the CSF and subsequent spread by implantation on meningeal surfaces.^{170, 286} These metastases tend to occur most commonly in the basal cisterns and in areas of relative CSF stasis.³¹⁷ The malignant infiltrate induces a reactive inflammatory response of the leptomeninges, and communicating hydrocephalus may develop as a result of obstruction of the basal cisterns or the pacchionian granulations.^{11, 286} Sources include most primary parenchymal neoplasms of the brain, even relatively low grade gliomas,⁶⁴ as well as carcinomas of the breast, lung, and gastrointestinal tract, melanoma, lymphoma, and leukemias, notably acute lymphatic leukemia.^{230, 286, 317} Of the secondary causes, carcinomas of the breast and lung are most common; in as many as 50% of patients with small cell carcinoma of the lung, leptomeningeal metastasis may be found at autopsy.³¹⁷

Leptomeningeal metastasis is nearly always symptomatic, and the simultaneous presentation of signs and symptoms in widely scattered areas of the CNS is typical.³⁴⁴ Headache is the most common initial complaint, occurring in 50% of patients, and weakness is found on clinical examination in 80%.³⁴⁴ Cranial nerve palsies are presenting complaints in 40% of patients, and lethargy and confusion are found in 20%.³⁴⁴ Although on occasion, the diagnosis of leptomeningeal metastasis may be established before the primary tumor becomes symptomatic, the interval between primary diagnosis of neoplasm and diagnosis of leptomeningeal involvement is typically between 6 months and 3 years; at this stage, most patients also have evidence of metastatic disease outside the CNS.³¹⁷ The diagnosis is usually established by lumbar puncture and microscopic examination of the CSF; abnormal cytologic results are obtained in approximately 50% of patients on the initial analysis and in 95% after six lumbar punctures.³⁴⁴ Supporting findings include elevation of CSF pressure above 160 mm Hg, increase in protein concentration above 20 gm/L, and elevated white blood cell count (usually lymphocytes), all of which are found in at least one half of patients.²²⁴

Although CT has proved highly sensitive for the detection of cerebral parenchymal metastases, leptomeningeal metastasis has been demonstrated on contrast enhanced CT images in less than a third of patients with cytologic evidence of CSF seeding.^{16, 116, 188} The sensitivity of MRI without and with paramagnetic contrast enhancement for detection of leptomeningeal metastasis appears to be approximately twice that of CT.^{118, 317, 318, 358} MRI findings strongly suggestive of leptomeningeal metastasis include (1) nodular or plaque-like thick curvilinear hyperintensity of the involved subarachnoid cisterns and spaces on FLAIR images and (2) homogeneous contrast enhancement on postcontrast T1-weighted images that diffusely involves one or more subarachnoid cisterns, coats the surfaces of the adjacent brain parenchyma, and extends into the sulci (Fig. 5-64).^{11, 118, 317, 358} The leptomeningeal tumor may also invade the underlying brain parenchyma and infiltrate the perivascular spaces surrounding the penetrating vessels.³¹⁷ The greater sensitivity of MRI for detecting leptomeningeal tumor spread has established this technique as the diagnos-

Figure 5-64. Leptomeningeal metastasis/carcinomatosis from carcinoma of the breast. Axial T1-weighted postgadolinium MR image. Numerous and diffuse nodular foci of leptomeningeal thickening with intense contrast enhancement are seen in the sylvian fissures, over the convexity surfaces, and in the convexity and parasagittal sulci bilaterally. A large nodule fills the pericallosal sulcus anteriorly (arrow). There is associated mass effect in the right frontotemporal region with resultant compression of the frontal horn of the right lateral ventricle and slight displacement of the third ventricle to the left of the midline.

tic modality of choice for the evaluation of possible leptomeningeal carcinomatosis.¹¹

The differential diagnosis of leptomeningeal contrast enhancement includes bacterial and fungal meningitis, sarcoid (see Fig. 5-54), and postoperative inflammatory changes in the meninges.^{11, 118, 258, 317} On the basis of imaging alone, definitive differentiation of tumor from inflammation or infection is not possible. Local or diffuse meningeal contrast enhancement at the site of previous craniotomy or at the site of insertion of a ventriculostomy shunt catheter reflects an inflammatory response of the traumatized dura and leptomeninges with eventual fibrosis.¹⁴⁶ Nodularity of the contrast enhancing tissue may favor neoplastic over inflammatory processes, but by no means is this true in all cases.^{146, 258, 317}

Cerebral Infections and Inflammation

Chi-Shing Zee, John L. Go, Paul Kim,
Hervey D. Segall, Jamshid Ahmadi

Since the advent of computed tomography (CT) scanning and magnetic resonance imaging (MRI), a significant decrease has occurred in the morbidity and mortality of patients with intracranial infections.¹²³ Although conventional cerebral angiography may be required in selected circumstances to confirm suspected vasculitis or mycotic aneurysm, CT and MRI studies are generally the modalities of choice in the evaluation of intracranial infection. CT and MRI, with stereotactic devices, have permitted biopsy of the intracranial focus of infection to identify the pathogen and subsequent drainage of abscesses through needle aspiration.¹⁴⁸ Recent advances in technology have allowed us to utilize additional imaging modalities in the evaluation of intracranial infection, such as positron emission tomography (PET), single photon emission computed tomography (SPECT), diffusion imaging, and magnetic resonance proton spectroscopy (MRS).

Two main sources of intracranial infection exist:

1. *Hematogenous*, in which infectious agents are carried to the meninges, corticomedullary junction, and choroid plexus by way of the bloodstream from a remote focus such as a lung infection; for instance, children with cyanotic heart disease have a high incidence of intracranial infection because of a right-to-left shunt. Retrograde venous spread can also occur via anastomotic connections between superficial veins of the face and scalp and cortical veins.
2. *Direct extension*, resulting from otitis media, mastoiditis, sinusitis, and open wounds from the trauma. In addition, certain viral infections can occur by spreading along the nerve in retrograde fashion.

Certain external factors appear to enhance the risk of intracranial infections (e.g., diabetes mellitus, alcoholism, malignancy, agammaglobulinemia, radiation or chemotherapy, steroid therapy). Patients with acquired immunodeficiency syndrome (AIDS) now account for a significant number of cases of intracranial infection, but the disease spectrum in these individuals is different. Various infectious processes involve the central nervous system (CNS). Pyogenic infection is discussed in detail in this chapter with categorization according to the anatomic site of involvement. Other infectious processes are also discussed, including viral infections, granulomatous disease, spirochete infections, fungal diseases, and parasitic diseases.

Meningitis

Meningitis is an inflammation of the dura, leptomeninges (the pia mater and the arachnoid membrane), and the

adjacent subarachnoid space.⁷² The diagnosis is usually made clinically. The role of neuroimaging is to exclude complications of meningitis (e.g., abscess, ventriculitis, empyema) that may call for different treatment. With appropriate window settings, CT scans may provide information regarding diseases of the paranasal sinuses or mastoids, which may be a source of intracranial infection. MRI studies are extremely sensitive in detecting diseases in the paranasal sinuses and the mastoids, especially on T2-weighted images.

In older people, *Streptococcus pneumoniae* and *Listeria monocytogenes* are often the causative agents. In young adults and older children, purulent meningitis is caused mainly by *Neisseria meningitidis*. In young children and infants, the cause may be *Haemophilus influenzae*, *S. pneumoniae*, and *N. meningitidis*. In infants younger than 1 month of age, causes include *Streptococcus agalactiae* (group B) and *Escherichia coli*.³⁶

The initial pathologic responses of the dura and leptomeninges to infection include vascular congestion, edema, and minute hemorrhages. CT and MRI findings may be normal early in the disease process^{21, 170} and remain normal with prompt and adequate treatment.

Once infection progresses, unenhanced CT scans frequently show obliteration of the basal cisterns. This probably results from a combination of hypervascularity in the acutely inflamed leptomeninges and exudate in the subarachnoid space. Diffuse cerebral swelling may be seen. Contrast-enhanced CT scans may show enhancement in the basal cisterns and sylvian fissure, regardless of the causative organism.

Routine MRI scans show obliteration of the basal cisterns on T1-weighted images. Contrast-enhanced MRI studies may show basal cisternal and sylvian enhancement as well as enhancement deep within the cortical sulci. Enhancement can be seen along the tentorium, falx, and the convexities—which can be better appreciated with MRI because of its greater contrast resolution^{20, 112, 138} (Fig. 6–1).

Early complications of meningitis include abscess, subdural empyema, ventriculitis, and infarction. Late complications include subdural effusion, encephalomalacia, hydrocephalus, and atrophy.^{21, 129}

On contrast-enhanced CT scans, the differential diagnosis includes meningeal carcinomatosis and subacute stage of subarachnoid hemorrhage. The clinical histories, however, are entirely different in these disease entities. The MRI differential diagnosis includes only meningeal carcinomatosis, since subacute subarachnoid hemorrhage shows

Figure 6-1. Meningitis. Gadolinium-enhanced MRI study shows enhancement along the tentorium, falx, and convexities.

distinct hyperintensity on T1-weighted images before injection of contrast material.

Contrast-enhanced MRI has been shown to be more sensitive than contrast-enhanced CT in detection of meningitis and its complications in experimental studies.⁹³ The radiology literature reports that abnormal contrast enhancement on intravenous (IV) gadolinium-enhanced MRI is seen in only 55% to 70% of patients with the clinical diagnosis of meningitis. The fluid attenuation inversion-recovery (FLAIR) technique is very sensitive and relatively specific in the diagnosis of intracranial subarachnoid space disease and meningeal disease.¹³⁵

Subdural Effusion

Subdural effusions are believed to be caused by irritation of the dura by the infectious agents or its by-products or by inflammation of subdural veins with loss of fluid and albumin into the subdural space.¹⁷ *H. influenzae* is a common pathogen associated with subdural effusion.¹² On neuroimaging, these effusions have a similar appearance to cerebrospinal fluid (CSF) and are frequently seen in the frontal region.¹³⁸ On contrast-enhanced imaging studies, there is no evidence of abnormal enhancement seen in the adjacent brain parenchyma. The subdural effusion usually resolves spontaneously without any treatment unless there is superimposed infection.

Subdural Empyema

Subdural empyema accounts for about 13% to 20% of all cases of intracranial infection. Subdural empyema is a collection of pus between the dura and the leptomeninges,

which often occurs as a complication of meningitis, paranasal sinusitis, otitis media, osteomyelitis, or a penetrating wound of the skull.^{73, 125}

Frontal sinusitis is the most common cause of subdural empyema. Infective organisms probably enter the subdural space in a retrograde fashion through a dural sinus or through bridging veins.¹²⁵ Occasionally, a subdural effusion induced by meningitis may become infected. Subdural empyemas, even when small, usually cause focal neurologic deficits in addition to acute febrile illness. Subdural empyema is considered a neurosurgical emergency because of its progressive clinical course. Despite recent improvement in surgical technique and antibiotics, mortality remains high (25% to 40%).¹²⁵

Complications of subdural empyema include venous thrombosis and infarction. On a CT scan, subdural empyema appears as a hypodense or isodense crescentic or lenticular area adjacent to the inner table of the skull.^{83, 99} On a contrast-enhanced CT scan, enhancement of the medial rim may be seen. Empyemas are better visualized with MRI than with CT. Empyemas show slightly higher intensity, compared with CSF, on both T1-weighted and T2-weighted images, which can help to differentiate them from sterile subdural effusion. The higher signal intensity is caused by the increased protein content of the empyema. On T2-weighted images, adjacent cerebritis or infarction may present as high-signal-intensity areas with irregular margins¹³⁸ (Fig. 6-2A). Enhancement of the medial rim is invariably seen (Fig. 6-2B and C); enhancement of the lateral rim adjacent to bony calvarium may sometimes be visible. Subdural empyemas may also be parafalcine,⁵⁴ and they may occur over the tentorium. Occasionally, enhancement of the subjacent cerebral cortex may be seen in a gyriform pattern in contrast-enhanced CT or MRI scans, suggesting the presence of concomitant cerebritis or infarction.

Epidural Empyema

Epidural empyema, a collection of pus between the dura and calvaria, occurs as a complication of otitis media, mastoiditis, sinusitis, or osteomyelitis of the skull.⁵⁹ Generally, infection in these patients is not as toxic as that in patients with subdural empyema. In addition to the presence of an extracerebral collection, imaging studies may show displacement of the falx and dural sinuses away from the inner table of the skull, which is an important and useful sign indicating the epidural location of a collection.⁷⁸

A hypointense rim, representing inflamed dura, is seen on T2-weighted MR images in an epidural, but not a subdural, empyema.¹⁵¹ Contrast-enhanced CT or MRI scans show a reasonably well-demarcated rim of enhancement representing inflamed dura. Because the dura usually acts as a barrier to organisms, the cerebral cortex beneath an epidural empyema is generally normal, and no enhancement in the underlying brain is seen.

Ten percent of epidural empyemas may be associated with subdural empyema (Fig. 6-3). An unenhanced CT scan shows a lentiform hypodense or isodense collection. MRI shows a slightly higher-signal-intensity collection, compared with CSF, on both T1-weighted and T2-weighted images because of the increased protein content of the pus.

Figure 6-2. Subdural empyema in a patient with sinusitis. *A*, T2-weighted image demonstrates high-signal-intensity extra-axial fluid collection in the right frontal convexity and along the falx on the right side. *B* and *C*, Gadolinium-enhanced MRI study shows extra-axial fluid collection in the right frontal convexity and along the falx with intense peripheral enhancement. The signal intensity of the fluid collection is slightly higher than that of cerebrospinal fluid.

Figure 6-3. Frontal epidural empyema and interhemispheric fissure subdural empyema. Lentiform low-density collection is seen in the frontal region with displacement of the sagittal sinus away from the inner table of skull. An interhemispheric subdural collection is also seen.

Encephalitis

Encephalitis refers to diffuse inflammation of the brain with a parenchymal infiltration of inflammatory cells, usually caused by a virus. The brain damage caused by acute infective encephalitis is due to a combination of intracellular viral growth and the host's inflammatory response.

The most common viral agents are herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2). Other causes include herpes zoster, arbovirus, and enteroviruses. Viral encephalitis in immunosuppressed patients can result from the human immunodeficiency virus (HIV), cytomegalovirus (CMV), and papovavirus. Other nonviral agents of encephalitis in immunosuppressed patients include *Toxoplasma*, *Aspergillus*, and *L. monocytogenes*.

Herpes Simplex Encephalitis

Herpes Simplex Type 1 Encephalitis

HSV-1 most commonly affects adults, whereas HSV-2 affects neonates. HSV-1 is the cause of 95% of all cases of herpetic encephalitis and is the most common cause of sporadic encephalitis. HSV-1 encephalitis is a fulminating, necrotizing meningoencephalitis that characteristically involves the temporal lobes and frontal lobes.

In the adult form, unenhanced CT scans show hypodense areas with mass effect in both temporal lobes and

frontal lobes; these changes are less likely to be observed in parietal lobes. The findings are often asymmetrical.^{27, 84} Sparing of the lenticular nucleus is said to be characteristic,¹⁷³ although such sparing may be observed in patients with infarction or glioma. An unenhanced CT scan infrequently shows hemorrhage in the low-density area early in the disease process, even though petechial hemorrhage is a frequent finding pathologically.

Contrast enhancement is a later finding in the disease process. Many published reports have documented uptake of technetium Tc 99m pertechnetate in various parts of the brain but most commonly in the temporal lobes. However, the scans become positive only at 2 days after the onset of clinical symptoms.^{44, 50, 58} There are published reports that hexamethyl-propyleneamineoxime (HM-PAO)-SPECT is capable of detecting increased activity early on in the disease process.⁴⁴

Enhanced CT scans show streaky, linear enhancement in the region of the sylvian fissure and the island of Reil⁹⁷ (Fig. 6-4). Unfortunately, CT studies, even high-resolution ones, show minimal changes, or results may be normal in the first 5 days despite the presence of obvious clinical symptoms. CT scans must be studied carefully to detect subtle changes that support the clinical diagnosis and to allow the institution of early antiviral therapy.

MRI studies show hypointensity on T1-weighted images and hyperintensity on T2-weighted images (Fig. 6-5). The temporal lobes and insular cortex are the areas of early involvement. The frontal lobe and the cingulate gyrus are involved later.⁶¹ The contrast enhancement pattern of MRI is similar to that of CT. MRI is more sensitive than CT for early findings, especially when FLAIR imaging is used.³ End-stage disease consists of encephalomalacia and atrophy in the previously involved areas; later, calcification may develop in these areas.

Definitive diagnosis is made either with positive fluorescein antibody staining or with a culture of the virus from a brain biopsy. Mortality is high, up to 70%. Successful treatment depends on early diagnosis and early institution of therapy before the onset of coma.¹⁵⁸

Herpes Simplex Type 2 Encephalitis

HSV-2 encephalitis may be acquired through the placenta or during delivery.^{41, 126} During the first trimester, HSV-2 encephalitis infection may have significant teratogenic effects on the fetal nervous system, including microphthalmia, encephalomalacia, and retinal dysplasia as well as mental and developmental retardation.^{102, 136, 139}

Initial CT abnormalities include low density in the white matter diffusely, not just in the temporal lobes, and finger-like areas of increased cortical density on unenhanced scans 2 to 30 days after presentation. A gyriform pattern of enhancement may be seen later.

MRI shows hypointensity in the white matter on T1-weighted images and hyperintensity on T2-weighted images. The enhancing pattern in MRI studies is similar to that on contrast-enhanced CT scans.

End-stage HSV-2 encephalitis may be characterized by cystic encephalomalacic change and cortical calcification.⁶² Periventricular calcification and parenchymal calcification

Figure 6-4. Herpes simplex encephalitis. *A* and *B*, A large low-density area is seen in the right temporal lobe with sparing of the lenticular nucleus. Significant mass effect has occurred with compression of the right lateral ventricle. *C* and *D*, Postcontrast scans show streaky linear enhancement in the region of the sylvian fissure.

are better seen on unenhanced CT scans than in MRI studies.³⁴ Mortality and morbidity rates are high.¹⁵⁸

Herpes Zoster Encephalitis

Herpes zoster encephalitis is thought to be secondary to reactivation of a latent viral infection of earlier chickenpox. It is more commonly seen in immunosuppressed patients.^{33, 65} CNS involvement is frequently seen in patients with skin lesions.

CT scans show multiple low-density lesions in the deep white matter. Hemorrhage may be seen as areas of poorly defined high density within the low density. MRI studies show hyperintensity in the deep white matter on T2-weighted images.

Herpes zoster virus has been implicated in the cause of granulomatous angiitis.^{85, 125} Small cerebral arteries are typically involved, although large vessels may also be affected (Fig. 6-6). Cerebral infarction or aneurysm formation may be seen.

Arbovirus Encephalitis

Human infection caused by arbovirus is transmitted from birds through ticks and mosquitoes. There are more than 250 types of arbovirus, including eastern and western equine encephalitis, St. Louis encephalitis, Japanese encephalitis, and so on. CT and MRI may show abnormalities intracranially without the propensity to involve any specific region.^{128, 132}

Figure 6-5. Herpes simplex encephalitis. A, T2-weighted image shows high signal intensity involving the gray and white matter of the right temporal lobe. Note the effacement of the adjacent cortical sulci, indicating the presence of mass effect. B, Gadolinium-enhanced image demonstrates no definite contrast enhancement in the early stage of disease. Low signal intensity with mass effect in right temporal lobe is obvious.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis is caused by an immune response to a preceding viral infection or vaccination. Patients usually present with neurologic signs and symptoms 5 days to 2 weeks later. Both humoral and cell-mediated immunity are implicated as the cause of pathologic changes. Vasculitis is thought to be caused by

complement activation as a result of antigen-antibody complexes. A hypersensitivity reaction to a myelin protein is thought to cause demyelination. Perivenous demyelination is the hallmark of the disease.

The disease primarily involves white matter, but change may also be apparent in gray matter and brain stem. CT may show low density in the periventricular white matter, and MRI may show hyperintensity in the white matter on T2-weighted images.^{67, 75, 89, 104} Some of the lesions may exhibit contrast enhancement following IV injection of gadolinium.

The differential diagnosis include multiple sclerosis, vasculitis, and embolic infarction. In later stages of the disease, encephalomalacia, ventriculomegaly, and atrophy may be seen.

Figure 6-6. Herpes zoster vasculitis. Magnetic resonance angiogram demonstrates narrowing of the left middle cerebral artery branches as well as the proximal left posterior cerebral artery. There is a small infarct in the left middle cerebral artery territory.

Other Encephalitides

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease is a human spongiform encephalopathy that results from an infection by a “slow virus.” The mode of transmission has been traced to inoculations by injections of human growth hormone, transplantation of corneas, and implantation of cerebral electrodes.¹¹⁸ In addition, butchers and meat handlers are at greater risk of contracting the disease. A new variant of Creutzfeldt-Jakob disease is due to bovine spongiform encephalopathy (so-called mad cow disease).

The infective prion is a proteinaceous particle that contains little or no nucleic acid. The disease occurs in adults

in their late 50s. However, the new variant of the disease can affect all age groups. Dementia with rapid progression to stupor is seen clinically. CT and MRI studies are useful to document the rapid progression of atrophy.^{78, 147} Cortical gray matter involvement without cerebral atrophy may represent an early phase of the disease.⁴⁵ Hyperintensity may be seen in cortical gray matter on T2-weighted images or FLAIR images, and on diffusion-weighted images, which may reflect areas of gliosis and microvacuolization pathologically.^{6, 28, 44}

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis is caused by the measles virus. Elevated levels of a neutralizing antibody to the virus can be detected in the blood and CSF. The disorder is usually seen in children and young adults. CT scans may show low-density changes in subcortical white matter as well as in basal ganglia. MRI studies show hyperintensity in the periventricular white matter and basal ganglia on T2-weighted images.¹⁴⁶ Atrophy is a late-stage finding.

Reye's Syndrome

Reye's syndrome is a disease of unknown etiology in children. It usually follows a viral infection such as type A or B influenza and varicella. Exogenous toxins, such as salicylates, and intrinsic metabolic defects have been implicated as being other factors associated with the disease.

Gross pathologic specimens demonstrate diffusely swollen brain. CT scans show diffuse low density of the supratentorial structures, a finding consistent with diffuse cerebral edema.¹²⁴

Rasmussen's Encephalitis

Rasmussen's encephalitis is a childhood disease. The child presents with severe epilepsy and progressive neurologic deficits.¹⁴³ Seizures are usually of the partial motor seizure type and tend to be intractable. The intractable nature of the seizure may make hemispherectomy necessary if medical therapy is ineffective.

Early in the disease process, CT and MRI findings may be normal. MRI may reveal hyperintensity in the white matter and putamen on T2-weighted images.¹⁴³ PET imaging using fluorodeoxyglucose-18 (FDG-18) may show decreased hemispheric activity.

Encephalitis in Immunocompromised Patients

Human Immunodeficiency Virus Encephalitis

HIV is a neurotropic virus, which typically causes a subacute form of encephalitis. CT scans may show low density in the periventricular white matter. MRI may show hyperintensity in the periventricular white matter on T2-weighted and FLAIR images.¹¹⁴ Normal neuroimaging studies do not exclude HIV encephalitis.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy is caused by papovavirus. It is uncertain whether it represents a reactivation of a latent infection. Pathologically, the major target cell is the oligodendrocyte. Because this cell is responsible for myelin maintenance, its destruction leads to demyelination.

CT scans characteristically show low density in the parietal and occipital white matter. Frontal involvement is seen later on. Early involvement may assume an asymmetrical pattern, but the changes in later disease are highly symmetrical and diffuse. Contrast enhancement is usually absent but may occur.¹⁵⁵ The presence of contrast enhancement may actually suggest the relative presence of host immunity and thus indicates a better prognosis.

MRI shows hypointensity in the white matter on T1-weighted images and hyperintensity on T2-weighted images (Fig. 6-7). MRI is more sensitive than CT in detecting abnormalities.⁵⁶

Cytomegalovirus Encephalitis

In immunocompromised patients, CMV may cause meningoencephalitis or subacute encephalitis.¹⁰⁶ CMV can produce demyelination and necrosis within the white matter.

CT scans show low density in the white matter, which may or may not enhance with contrast agents. MRI shows high signal intensity in the white matter on T2-weighted images and is more sensitive than CT in detecting leukoencephalitis.⁹²

Figure 6-7. Progressive multifocal leukoencephalopathy. T2-weighted image shows high signal intensity in the parieto-occipital white matter bilaterally.

Neonatal cytomegalic inclusion disease is a severe disseminated necrotizing encephalitis with a tendency to involve the periventricular tissue. Unenhanced CT scans show periventricular calcification with ventricular dilatation⁴ (Fig. 6–8).

Cerebritis and Abscess

Pathologically, there are four stages in the evolution of cerebral abscess as demonstrated by experimental studies by Enzmann and colleagues³⁸:

1. *Acute cerebritis* (the first 4 to 5 days). The organism grows in the parenchyma. Acute inflammatory cells, particularly polymorphonuclear leukocytes, migrate into the parenchyma to ingest or destroy bacteria. Opening of the blood-brain barrier produces edema. Microscopic hemorrhage may be seen during the acute cerebritis stage but is unusual later.
2. *Late cerebritis* (at 7 to 10 days). The small areas of necrosis coalesce into one large focus filled with necrotic debris. Granulation tissue forms at its margin, containing macrophages. Edema and small foci of cerebritis are seen surrounding this area. These small foci later form satellite lesions adjacent to the large abscess.
3. *Early abscess* (at 10 to 14 days). Formation of a collagenous capsule by fibroblasts is seen. The central necrotic area is liquefied. Surrounding edema persists.
4. *Mature abscess* (>14 days). A decrease in surrounding edema is seen. A gliotic reaction develops at the outer margin of the abscess capsule. The wall of the mature abscess consists of three layers: (1) an inner inflammatory layer of granulation tissue containing macrophages,

(2) a middle collagenous layer, and (3) an outer gliotic layer.¹⁷²

Acute cerebritis is not often identified on neuroimaging studies because symptoms do not usually develop until later.¹³⁹ Initially, acute cerebritis usually manifests in white matter with vascular congestion and edema, so that ill-defined areas of low density and mass effect in the white matter are noted on unenhanced CT scans.^{21, 101} On MRI studies, edema is seen as hypointensity on T1-weighted images and hyperintensity on T2-weighted images. MRI is superior to CT in detecting cerebral edema and subtle mass effect.^{57, 128}

In early cerebritis, mild central nodular enhancement may be seen on contrast-enhanced CT or MRI scans (Fig. 6–9). In the late cerebritis stage, experimental studies of the evolution of brain abscess following inoculation of organisms have demonstrated brain enhancement on CT scans.³⁸ On MRI studies, the enhancing pattern is similar to that with CT. A relatively thick, slightly irregular, ringlike enhancement is seen interposed between the peripheral edema and central necrosis (Fig. 6–10).

As the lesion matures, the ringlike enhancement becomes thinner and smoother. The most distinctive feature of abscess on imaging is the presence of a smooth, thin capsule with a moderate amount of cerebral edema.⁵⁷ It is located at the corticomedullary junction and usually extends into the white matter. The abscess cavity has necrosis and liquefaction within its center. Unenhanced CT scans show a low-density area with mass effect and compression of the ventricular system. Between the central low-density area (representing the cavity) and the surrounding low-density edematous zone, a ring of higher density may be seen.^{70, 137, 153} Visualization of spontaneous gas within the

Figure 6–8. A and B, Cytomegalic inclusion disease. Unenhanced CT scan in a newborn shows periventricular calcification and ventricular dilatation.

Figure 6-9. Early cerebritis. A, T2-weighted image demonstrates a low-signal-intensity focus with surrounding high-signal-intensity edema. B, Gadolinium-enhanced MRI study shows nodular enhancement with surrounding edema.

Figure 6-10. Late cerebritis. A, Gadolinium-enhanced MRI study shows thick, smooth, ringlike enhancement with surrounding edema. B, Gadolinium-enhanced MRI study (coronal view) shows a second, small, adjacent ringlike enhancement.

abscess cavity indicates the presence of gas-forming organisms^{99, 101} (Fig. 6–11). Contrast-enhanced CT scans show ringlike enhancement, which is usually thin and uniform in thickness. Occasionally, thick irregular ring enhancement may be seen—especially following partial treatment—and may mimic neoplasm.

The CT features of abscess vary, depending on the function of the host reaction to infection and different stages in the evolution of the abscess.^{97, 172} On MRI scans, the capsule is better visualized as compared with CT. The capsule is isointense to hyperintense to gray matter on T1-weighted images and hypointense on T2-weighted images. The hypointensity on the abscess capsule is consistently seen with abscess and may be useful in characterizing the lesion⁵⁷ (Fig. 6–12A). However, other lesions, such as metastasis, glioma, and cysticercosis, may show a similar hypointense ring on T2-weighted images. The capsule enhances with IV administration of contrast material on CT or MRI studies.

The presence of satellite lesions is a unique feature of cerebral abscess (Fig. 6–12B). Firmness of the capsule wall depends on how long the lesion has been present. Usually, more than 2 weeks is required to form a firm capsule. Clinical improvement with medical therapy has been correlated with a decrease in both the degree of ring enhancement and the amount of surrounding edema (Fig. 6–13).^{71, 121}

A serious fulminating complication is rupture of the abscess into an adjacent ventricle. Abscesses tend to rupture medially into the ventricular system because the medial wall is thinner than the lateral wall.¹⁵³ This is related to the white matter having less vascular supply than gray matter. A more intense perivascular response is seen at the site of gray matter.¹³⁷

The differential CT diagnosis of cerebral abscess includes primary or metastatic neoplasm, subacute infection, and resolving hematoma. The enhancing ring of an abscess is usually thinner and more uniform than that found in the neoplasm. Granulomatous abscesses tend to have a thicker ring than pyogenic abscesses and have less surrounding edema. Infarcts often show gyral enhancement, occasionally mimicking ring enhancement. Resolving hematoma may have a dense center with ringlike enhancement and much less surrounding edema.

The MRI differential diagnosis of abscess is similar to the CT diagnosis except for hematomas, which can be recognized by their characteristic MRI signal intensity patterns, depending on the age of the hematomas.

Various authors have given different explanations of capsular hypointensity.^{68, 139, 171} The most plausible hypothesis seemed to suggest that macrophages within the granulation layer of the abscess capsule are the cause of the hypointensity. Macrophages kill bacteria with respiratory burst, during which molecular oxygen is converted into atomic oxygen, which then generates a series of short-lived highly reactive oxygen free radicals that interact with the bacteria. Because these free radicals are intracellular, they may be capable of producing similar susceptibility effects as intracellular methemoglobin or deoxyhemoglobin with resultant T2 shortening.^{68, 139, 171}

The features of abscess tend to differ in immunocompromised patients receiving steroids. In such patients, edema may be minimal and the abscess capsule may be thick and irregular. Hypointensity of the capsule seen on T2-weighted images may not be obvious. Extraparenchymal spread into the ventricles and meningitis are more common.

The differential diagnosis of brain abscesses is quite

Figure 6–11. Abscess caused by gas-forming organism. A, Gas is seen with a surrounding low-density area on noncontrast CT scan. B, Contrast CT scan shows irregular, ringlike enhancement; gas is visible within the cavity. The causative organism was *Escherichia coli*.

Figure 6-12. Mature abscess. *A*, T2-weighted image shows a mature abscess with hypointense rim, central cavity, and adjacent surrounding edema. A small satellite lesion is also seen. *B*, Gadolinium-enhanced MRI study demonstrates smooth, ringlike enhancement corresponding to the hypointense rim seen on T2-weighted images.

extensive and includes necrotic primary brain tumor, cystic metastatic tumor, infarction, resolving hematoma, cysticercosis, and thrombosed aneurysm. Thallium 201 SPECT or PET may be useful in differentiating an abscess from a necrotic tumor. Preferential uptake of thallium is seen in tumor, especially high-grade tumor, but not in abscess.⁴⁴ Tumor has higher glucose utilization than that of abscess, as shown on FDG PET imaging.

Recently, much work has been done with advanced imaging techniques such as diffusion-weighted imaging and proton MRS. The central portion of an abscess cavity tends to show depression of apparent diffusion coefficient, thus increased signal intensity on diffusion-weighted images (Fig. 6-14), whereas tumor necrosis exhibits an increase in apparent diffusion coefficient.

A significant number of studies of proton MRS have been performed in differential diagnosis of abscess and necrotic brain tumors. It is well documented that abscess cavities contain amino acids, succinate, and acetate, which are not seen in the necrotic center of the tumor.³⁰ Furthermore, MRS may be useful as the follow-up examination in evaluation of the response to therapy.³¹

Mycotic Aneurysm

Intracranial septic emboli may lead to the formation of mycotic aneurysms, usually seen in patients with a history of IV drug abuse, cyanotic heart disease, and subacute bacterial endocarditis. Mycotic aneurysms probably result from infarction of the arterial wall secondary to infected

emboli. Mycotic aneurysms may be solitary or multiple, and they usually involve middle cerebral artery branches. The relative frequency of middle cerebral artery branch involvement is probably explained by the likelihood of emboli being carried into this territory.

Rupture of a mycotic aneurysm may produce an intracerebral or subdural hematoma¹³⁴ (Fig. 6-15). An unruptured mycotic aneurysm may occasionally be detected by contrast-enhanced CT or MRI studies.² Associated infarction or small areas of cerebritis or abscess formation may be seen on imaging. Follow-up imaging studies can be useful when mycotic aneurysms are being treated medically with antibiotics. A single mycotic aneurysm may warrant surgical extirpation.

Ependymitis

Ventriculitis, or ependymitis, is an inflammation of the ependymal lining of the ventricular system. Spread of infection to the ventricles may result from rupture of a periventricular abscess or from retrograde spread of infection from the basal cisterns by way of the fourth ventricle. Hydrocephalus may result from intraventricular adhesions and septation caused by organization of intraventricular exudate and debris, resulting in blockage of the interventricular foramina.^{129, 166} A trapped fourth ventricle may result from obstruction of its outlets and the aqueduct because of ependymitis.¹⁶⁹

The noncontrast CT scan may be normal or may show only slightly increased density in the region of the affected

Figure 6-13. Abscess treated conservatively with antibiotics. *A*, T1-weighted image shows a low-signal-intensity mass with an isointense ringlike rim and surrounding edema in the left posterior temporal lobe. *B*, T2-weighted image shows a high-signal-intensity mass with low-signal-intensity rim and marked surrounding edema. *C*, Gadolinium-enhanced image demonstrates avid ringlike enhancement of the ringlike rim with a central cavity and surrounding edema. *D*, Follow-up T2-weighted image obtained 8 weeks later reveals a significant decrease in the size of the abscess and surrounding edema. *E*, Follow-up gadolinium-enhanced image demonstrates minimal residual enhancement.

Figure 6-14. Mastoiditis, cerebritis, and abscess formation. *A*, T1-weighted image shows abnormal low signal intensity in the left temporal lobe, left brachium pontis, and left mastoid. *B*, T2-weighted image shows heterogeneous high signal intensity involving the left temporal lobe, left brachium pontis, and left mastoid. *C*, Gadolinium-enhanced image demonstrates abnormal enhancement involving the left temporal lobe, left brachium pontis, and left mastoid. Note the presence of a small ringlike enhancement in the posterior aspect of the brachium pontis. *D*, Diffusion-weighted image reveals a focal area of increased signal intensity, corresponding to the ringlike enhancement. This is consistent with restricted diffusion in an abscess.

Figure 6-15. Mycotic aneurysm. *A*, Proton-density-weighted image shows high-signal-intensity hemorrhage in the left occipital lobe as well as in the ventricle. A small, ringlike, low-signal-intensity area is seen within the hemorrhage. *B*, A mycotic aneurysm was found on cerebral angiogram, corresponding to the small, ringlike, low-signal-intensity area seen on the MRI study.

ependyma.^{101, 170} MRI studies may show marginal ventricular abnormality or only slightly increased signal intensity in the region of affected ependyma on proton-density-weighted images. The fluid within the ventricles may show slightly increased intensity, indicating the presence of cells and inflammatory debris as well as increased protein concentration in the CSF.

Contrast-enhanced CT or MRI studies show uniform, thin ependymal enhancement (Fig. 6-16).

The differential diagnosis on CT and MRI studies includes ependymal seeding of intracranial neoplasm. The ependymal enhancement may be irregular or nodular if it is secondary to seeding of neoplasm. Obviously, the clinical history may be helpful in arriving at the correct diagnosis.

Granulomatous Infection

Tuberculosis

Tuberculosis meningitis results from the hematogenous spread of bacilli from a primary lesion in the chest or genitourinary tract or from direct extension from an intracerebral focus. Primarily, very young and very old persons are affected, with the highest incidence in the first 3 years of life.¹¹¹ More recently, an increased incidence of tuberculosis has been seen in immunocompromised patients. In the patient with tuberculous meningitis, the exudate, which is commonly seen in the basal cisterns, tends to be thick and adhesive. Communicating hydrocephalus may result from obstruction at the level of the basal cisterns. Vascular

involvement of the arteries at the base of the brain or sylvian fissures may result from vasculitis and surrounding meningeal inflammation.

On noncontrast CT or MRI studies, the basal cisterns and sylvian fissures may be partially or completely obscured by the presence of purulent exudate and inflammatory tissue, which appears to have a density or signal intensity similar to that of the adjacent brain on CT scans or T1-weighted MRI studies, respectively.

On contrast-enhanced CT or MRI studies, the involved cisterns show intense enhancement^{5, 16, 138, 154} (Fig. 6-17). MRI studies are more sensitive than CT scans for detection of tuberculous meningitis.¹⁴ Ischemic infarcts, meningeal enhancement, and ventriculitis are better shown by MRI than by CT. Gadolinium injection is essential in evaluation of patients with intracranial tuberculosis. Calcification in the basal cisterns has been demonstrated a few years after the onset of disease and is better shown with CT scans.⁸⁷ Cerebral infarction may result from arterial or venous involvement. Middle cerebral artery territory is a common location⁹ (Fig. 6-18).

Arriving at a definitive diagnosis of tuberculoma may be difficult because 52% of patients with intracranial tuberculomas have no extracranial disease.⁹⁴ Tuberculomas may be found in any portion of the intracranial compartment. Histologically, tuberculomas consist of a central zone of caseous material surrounded by reactive epithelial cells, Langhans' giant cells, polymorphonuclear cells, plasma cells, and lymphocytes.¹⁵⁴

Figure 6-16. Ependymitis. *A* and *B*, Gadolinium-enhanced MRI study shows thin, smooth ependymal enhancement in an AIDS patient with cytomegalovirus ependymitis.

Figure 6-17. Tuberculous meningitis. *A*, Noncontrast CT scan shows high-density material in the suprasellar cistern, sylvian cistern, and perimesencephalic cistern. Dilation of both temporal horns is seen. *B*, Contrast CT scan shows diffuse intense enhancement in the involved cisterns.

Figure 6-18. Cerebral infarction as a complication of tuberculous meningitis. *A*, Large low-density area is seen in the right temporal frontoparietal region in the right middle cerebral artery distribution, consistent with an infarct. *B*, Enhancement is seen in the sylvian fissures and along the tentorial margin, consistent with meningitis.

On unenhanced CT scans, tuberculomas may be isodense, hyperdense, or of mixed density. On contrast-enhanced CT scans, tuberculomas may present a pattern of ringlike enhancement¹⁵² or, less likely, areas of nodular enhancement (Fig. 6-19) or irregular nonhomogeneous enhancement.^{21, 109, 116} A central nidus of calcification with surrounding ringlike enhancement, known as the *target sign*, suggests tuberculoma.¹⁵²

Gadolinium-enhanced MRI studies show enhancing patterns similar to those on contrast-enhanced CT scans^{20, 29} (Fig. 6-20). Unenhanced MRI studies show mixed, predominantly low-signal-intensity lesion with a central zone of high signal intensity and surrounding high-signal-intensity edema on T2-weighted images or FLAIR images. A central high-signal-intensity zone on T2-weighted or FLAIR images corresponds to caseating necrosis. The low signal intensity of the capsule may be related to a layer of collagenous fibrosis with high protein concentration and low water content and a layer of outer inflammatory cells.¹³⁰

On MRS, tuberculomas show only lipid resonance, with specific components of serine and phenolic lipids.¹³⁰ Follow-up CT or MRI studies are useful in monitoring the response to medical treatment.

Parenchymal infection of tuberculosis may occur with or without meningitis. Tuberculosis cerebritis or abscess may have an appearance on neuroimaging studies similar to that of pyogenic bacterial infection. Tuberculous abscess is rare and is characterized by a central area of liquefaction

with pus (Fig. 6-21). These abscesses should not be confused with tuberculomas with central caseation and liquefaction mimicking pus.^{52, 156}

Continued growth of tuberculoma with unresponsiveness to therapy, despite adequate medical treatment, is a known phenomenon called *paradoxical expansion*. Various immunologic mechanisms have been advanced as explanations, including defective local tissue immune response and poor penetration of drugs.¹³⁰

Sarcoidosis

The intracranial compartment is involved in 15% of patients with known sarcoidosis.^{24, 120, 133, 150} On rare occasions, CNS involvement may be the sole manifestation of sarcoidosis.^{13, 53} Sarcoid is more prevalent in the 3rd and 4th decades of life. It may present as leptomeningitis or intracerebral granulomas. A third form of sarcoidosis, meningoencephalitis, is rarely seen.⁹⁶ Granulomatous meningitis often involves the basal cisterns in the region of the optic chiasm and hypothalamic-pituitary axis. Hydrocephalus may occur as a result of obstruction at the aqueduct, fourth ventricle, or leptomeninges.^{80, 90}

Contrast-enhanced MRI is the imaging modality of choice for evaluation of meningeal sarcoidosis. Solitary or multiple lesions involving the meninges may be seen, and occasionally they may present as a large extra-axial mass (Fig. 6-22). The lesions are hypointense to isointense to

Figure 6-19. Tuberculoma. *A*, Noncontrast CT scan shows an isodense area with surrounding edema in the right frontal region. *B*, Contrast CT scan demonstrates nodular homogeneous enhancement.

Figure 6-20. Tuberculoma. *A*, T2-weighted image shows an area of high signal intensity in the left temporal lobe. *B*, Gadolinium-enhanced MRI study demonstrates multiring enhancement with surrounding edema.

Figure 6-21. Tuberculous abscess. *A*, T1-weighted image shows isointense to hyperintense capsules with central pus and debris and surrounding edema. *B*, T2-weighted image shows the abscess capsules with an inner ring of hypointensity and an outer ring of hyperintensity; pus shows hyperintensity, and debris shows hypointensity. *C*, Gadolinium-enhanced MRI study shows smooth ringlike enhancement of the abscess capsule.

Figure 6-22. Sarcoid. A, T1-weighted image shows an isointense extra-axial lesion near the vertex. B, T2-weighted image shows the lesion to be of low signal intensity. C, Gadolinium-enhanced MRI study demonstrates intense enhancement of the lesion, which is better shown as compared with unenhanced images.

brain on T1-weighted images and are of variable but frequently low signal intensity on T2-weighted images. Homogeneous enhancement is seen with contrast-enhanced MRI as with contrast-enhanced CT.

The differential diagnosis may include meningiomas, metastatic disease, and lymphoma. Diffuse meningeal disease is more common than focal disease in sarcoidosis. Leptomeningeal enhancement involving the basal cisterns can be seen on contrast-enhanced MRI studies (Fig. 6-23).¹³¹ However, a normal contrast-enhanced MRI study does not exclude the possibility of meningeal sarcoidosis.

The differential diagnosis of basal leptomeningeal enhancement may include bacterial, tuberculous, fungal, or cysticercal meningitis and meningeal seeding from metastasis, lymphoma, or leukemia. The noncaseating granulomas may be single or multiple, sometimes mimicking primary or metastatic neoplasm.^{53, 127, 133}

On unenhanced CT scans, the granulomatous lesion shows hyperdense or isodense areas with minimum surrounding edema. Contrast-enhanced CT scans reveal homogeneous enhancement of these lesions.⁷⁴ Improvement with a decrease in size and number of lesions may be observed following steroid treatment. The intracranial granulomas may be single or multiple in the cortical or subcortical region.

On MRI studies, the lesions show heterogeneous and hyperintense signal pattern on T2-weighted images. Contrast-enhanced MRI studies show homogeneous enhancement.^{60, 131} The differential diagnosis may include primary or metastatic neoplasms. Occasionally, meningeal disease

extends into the deep cortical tissue and may mimic a parenchymal lesion. Diffuse periventricular white matter high-signal-intensity lesions on T2-weighted images are among the most common findings in neurosarcoidosis. The areas of involvement may show enhancement following IV injection of gadolinium. These lesions are probably secondary to involvement of the small arteries in the white matter.^{60, 76, 131}

In the rare form of meningoencephalitis, contrast-enhanced CT scans may show linear and nodular meningeal enhancement extending into the parenchyma through the Virchow-Robin spaces.⁹⁶ Hypodense lesions in the white matter have been described and are probably secondary to involvement of the small arteries in the white matter.⁷⁶

SPIROCHETE INFECTION

Lyme Disease

Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is transmitted by deer ticks.¹⁰⁷ *Borrelia* is a neurotrophic bacterium that can produce acute neurologic symptoms or can remain dormant for many years.

Like syphilis, Lyme disease presents clinically in stages. The characteristic finding in the *early* stage is the skin rash known as erythema chronicum migrans seen at the site of tick bite.⁷⁹ Flulike symptoms and arthralgia associated with regional lymphadenopathy are also seen in the early stage. A disseminated form of early Lyme disease can occur in

Figure 6-23. Sarcoidosis. A, Fluid-attenuating inversion recovery (FLAIR) image shows diffuse, irregular, abnormal high signal intensity extending from the subarachnoid space into the brain parenchyma of frontal lobes and basal ganglia. B, Gadolinium-enhanced image demonstrates patchy contrast enhancement involving the frontal lobes and basal ganglia.

which the organs primarily involved are skin, joints, heart, and nervous system.

Late symptoms occur in approximately 10% of untreated patients. Signs and symptoms of chronic neurologic damage include headache, memory impairment, papilledema, irritability, facial palsy, and peripheral neuropathies.

In many patients, neuroimaging studies may be normal. MRI findings, when present, include multiple bilateral periventricular, subcortical white matter, basal ganglia, and brain stem hyperintense lesions seen on T2-weighted or FLAIR images. The lesions are said to resemble multiple sclerosis plaques.^{46, 119} Peripheral enhancement of these lesions may be seen. In some patients, diffuse meningeal enhancement is seen, indicating the presence of an encephalopathic process.

Syphilis

Syphilis is usually a sexually transmitted disease caused by *Treponema pallidum*, and CNS involvement occurs in the tertiary stage. Patients with AIDS usually show CNS involvement earlier, within 3 to 18 months. Acute syphilitic meningitis is a common manifestation in HIV-positive patients who are infected by *T. pallidum*.

Neurosyphilis can be divided into (1) meningovascular syphilis and (2) syphilitic gumma.

Meningovascular Syphilis

Pathologically, meningovascular syphilis is manifested by widespread thickening of the meninges, with lymphocytic infiltration involving the meninges and around the small vessels.¹⁰⁸ CT shows multiple low-density areas involving both gray and white matter.⁴⁸ Contrast-enhanced CT scans show linear, nonhomogeneous enhancement.

MRI is superior to CT scans in demonstrating additional foci of abnormality.⁶⁴ Contrast-enhanced MRI studies may demonstrate meningeal enhancement in addition to a gyri-form pattern of enhancement.

Syphilitic Gumma

Gummas consist of masses of granulation tissue and are rare. They originate in the meninges and blood vessels and spread into the brain parenchyma.

On CT scans, gummas are well-delineated masses with ringlike or nodular enhancement. On MRI scans, gumma shows a high-signal-intensity ring on T1-weighted images and low signal intensity with surrounding high-signal-intensity edema on T2-weighted images. On contrast-enhanced MRI, gumma shows nodular or ringlike enhancement. Cerebral atrophy may develop in patients with neurosyphilis.⁵¹

Fungal Disease

Fungal infection may involve intracranial blood vessels, leptomeninges, and brain parenchyma. Intracranial infection is frequently secondary to pulmonary disease. Prior to the era of immunosuppressive therapy in organ transplant patients and the increase in HIV infection, fungal infection

of the CNS was rare. Other conditions that predispose patients to fungal infection include diabetes, pregnancy, and malignancy.

Depending on the genera, fungi may exist as single cells (yeast) or in a branched appearance (hyphal form). The yeast and hyphal forms may coalesce and form mycelia. The fungi of yeast forms tend to spread hematogenously to the meningeal microcirculation, with resultant leptomeningitis attributable to their smaller size; the larger hyphal form more commonly involves the brain parenchyma, with resultant cerebritis or encephalitis.

The genera that are present predominantly as yeast forms include *Blastomyces*, *Candida*, *Coccidioides*, *Cryptococcus*, *Histoplasma*, *Paracoccidioides*, and *Torulopsis*. Hyphal forms include *Aspergillus*, *Mucor* and other agents of mucormycosis, and *Pseudoallescheria*.⁴⁹

CNS fungal infection displays neuroimaging features similar to those seen with tuberculosis. It is known that CT scanning underestimates the extent of the disease in patients with widespread fungal infection, and MRI probably better represents the extent of the disease. CT or MRI findings are not specific for various types of fungal infection.

Aspergillosis

Aspergillus fumigatus infection is seen predominantly in immunocompromised patients.²⁶ CNS aspergillosis is more commonly caused by hematogenous spread of pulmonary disease and less commonly caused by direct extension of disease in the nasal cavity and paranasal sinuses. Pathologically, diffuse vascular invasion with thrombosis of cerebral vessels occurs.¹⁶¹ Necrotizing arteritis of small vascular channels is also seen.

CT scans show low-density areas with little or no contrast enhancement and mass effect, representing areas of infarction.^{40, 55} At times, hemorrhagic infarction may be seen. Cerebritis or abscess formation may also be seen secondary to hematogenous spread of the disease. CT scans show a slightly hyperdense, ringlike lesion with central low density and surrounding edema. Some contrast enhancement may be seen.⁷⁷ Focal areas of hemorrhage within the lesion may be seen.¹⁴⁸

MRI studies demonstrate a peripheral ring of low signal intensity with an isointense (to gray matter) center and high signal surrounding edema on T2-weighted images. The ring of low signal intensity corresponds to a dense population of *Aspergillus* hyphal elements and small areas of hemorrhage histologically.

Coccidioidomycosis

Coccidioidomycosis is caused by the airborne fungus *Coccidioides immitis*. This fungus is endemic in the southwestern United States as well as in portions of Mexico and central South America.

Pathologically, coccidioidomycosis is characterized by thickened, congested leptomeninges and multiple granulomas in the basal cisterns. Meningitis is most intense at the base of the brain. Hydrocephalus is seen as a result of

granulomatous meningitis.¹⁰ Meningeal involvement is the most common manifestation of CNS disease, occurring in up to 50% of the patients with disseminated systemic disease. Males are affected five to seven times more commonly than females. Adult nonwhites often have acute, rapidly fatal meningitis, whereas children and adult whites usually have subacute or chronic meningitis.

Unenhanced CT or MRI studies show isodense or isointense granulomatous tissue filling the basal cisterns. Contrast-enhanced CT or MRI studies show extensive basal cisternal or convexity enhancement (Fig. 6-24). Parenchymal granulomas occur infrequently; ringlike enhancement with minimum surrounding edema may be seen on contrast-enhanced CT or MR studies^{35, 40, 98} (Fig. 6-25).

A lytic lesion involving the calvarium may be seen without parenchymal disease. Hydrocephalus may be secondary to meningitis or ependymitis. Small-vessel arteritis occurs in 40% of patients with meningitis, resulting in cerebral ischemia or infarction.⁴⁹

Cryptococcosis

Cryptococcosis is a systemic infection that is worldwide in distribution. Despite the high prevalence of cryptococci in the environment, cryptococcal infection is uncommon but commonly occurs in immunocompromised patients. A selective impaired lymphocyte response to cryptococci in otherwise healthy patients has been demonstrated.¹¹¹ Cryptococcosis is the most common fungal infection in patients with AIDS.

CNS infection is usually secondary to pulmonary infection. Cryptococcosis is the most frequent clinically encountered CNS fungal infection. CNS cryptococcosis may present as meningitis, meningoencephalitis, or cryptococcal

mass. Meningitis is the most common presentation. Hydrocephalus is seen as a result of the meningitis. Meningeal infection may extend from the basal cistern via dilated Virchow-Robin spaces into the basal ganglia and thalami.¹⁴⁴ Visual symptoms are common in patients with cryptococcal meningitis.

Two mechanisms have been implicated in patients with visual loss and optic atrophy: (1) increased intracranial compression with resultant damage to the optic nerve, and (2) direct cryptococcal involvement of the optic nerve.^{103, 140}

Contrast-enhanced CT or MR studies may show meningeal enhancement involving the basal cisterns, sylvian fissure, and cortical sulci; nodular or ringlike enhancement may be seen²⁵ (Fig. 6-26). Dilated Virchow-Robin spaces may be seen on CT scanning or MR imaging, which is highly suggestive of cryptococcosis.¹⁴⁴

On contrast-enhanced MR images, enhancement within the Virchow-Robin space may be seen (Figs. 6-27 and 6-28). However, similar findings may be seen in coccidioidomycosis and candidiasis. Optic atrophy is better demonstrated by MRI than by CT.

Mucormycosis

Mucormycosis occurs in immunocompromised patients, most often in patients with poorly controlled diabetes. There are two forms of CNS mucormycosis:

1. The common form is rhinocerebral infection, with or without intracranial extension, with a predilection for patients with diabetes.⁴³
2. The rare form is focal intracerebral infection in the absence of sinus disease. It is most often encountered in IV drug users. Anatomically, there is a predilection for the basal ganglia.¹⁴¹

Figure 6-24. Coccidioidomycosis meningitis. A, T1-weighted image shows isointense granulomatous tissue in the suprasellar cistern. B, Gadolinium-enhanced image demonstrates intense enhancement in the basal cisterns.

Figure 6-25. Coccidioidomycosis. *A*, Contrast-enhanced CT scan shows small lesions with ringlike enhancement. *B*, T2-weighted image shows two small low-signal rings with intermediate center and high-signal adjacent edema. *C*, Gadolinium-enhanced MRI study shows small lesions with ringlike enhancement and an adjacent area of patchy enhancement. The lesions are better shown with MRI than with CT.

Figure 6-26. Cryptococcosis. Contrast CT scan shows a ringlike enhancement in the right posterior temporal lobe with surrounding edema.

Rhinocerebral mucormycosis spreads from the nasal cavity and paranasal sinuses by means of perivascular perineural channels through the cribriform plate into the frontal lobe and through the orbital apex into the cavernous sinus.⁸² Pathologically, there is a predilection for the vasculature, particularly the arteries. It proliferates along the internal elastic lamina of the arterial walls, and hyphae may penetrate through the endothelium into the lumen, causing thrombosis with resultant infarction.

In the appropriate clinical setting, extensive paranasal sinus disease, with or without intracranial or nasopharyngeal extension, on CT or MRI studies should suggest mucormycosis. Extension of mucormycosis through bony partitions may occur without radiologic evidence of bone destruction.⁴⁷ Unenhanced CT scans may show low-density areas intracranially.

Contrast-enhanced CT scans may show ringlike enhancement with little surrounding edema. On MRI studies, sinus disease may exhibit near signal void (similar to air) on T2-weighted sequences, indistinguishable from normal aerated sinuses, which some suggest is the result of a high concentration of iron and manganese within the fungal mass.¹⁴¹

Primary intracerebral mucormycosis may reveal low density on unenhanced CT scans. Patchy, irregular enhancement is seen on contrast-enhanced CT scans. Focal

Figure 6-27. Cryptococcosis meningitis. A, T2-weighted image shows multiple small high-signal-intensity areas in the basal ganglia, consistent with a dilated Virchow-Robin space. B, Gadolinium-enhanced MRI study demonstrates small nodular enhancement, corresponding to the high signal intensity seen on T2-weighted images.

Figure 6-28. Cryptococcosis meningitis. **A**, Fluid-attenuating inversion recovery (FLAIR) image shows multiple high-signal areas in the basal ganglia as well as in the cortical sulci and subcortical white matter. **B**, Gadolinium-enhanced image demonstrates curvilinear abnormal enhancement in the basal ganglia and cortical sulci.

areas of hemorrhage may be seen within the lesion. With MRI, low signal intensity is seen on T1-weighted images, and areas of high signal intensity, mixed with very low signal intensity (near signal void), are seen on T2-weighted images. Patchy enhancement may be seen on contrast-enhanced MR images¹²⁸ (Fig. 6-29).

Candidiasis

Candida albicans is part of the normal flora in the gastrointestinal (GI) tract and mucocutaneous regions. *Candida* is also present in the vagina of healthy nonpregnant females and, more frequently, in pregnant females. *C. albicans* is the most common cause of human fungal infection⁸ and represents 75% of the fungal infections in patients with neoplasm. Candidiasis occurs in immunocompromised patients. Systemic candidiasis is an opportunistic mycosis, with the GI tract being the usual portal of entry. Any organ may be involved in systemic candidiasis including kidney, GI tract, brain, and respiratory system. CNS involvement occurs as a result of hematogenous spread or direct invasion from the oral cavity or orbit. There is a higher incidence of renal and cardiac candidiasis in patients with intracranial disease. Approximately 80% of patients with myocardial or valvular involvement have had cerebral candidiasis. Candidiasis may present as meningitis, granuloma, or microabscess.

Unenhanced CT scans usually show low-density areas. Contrast-enhanced CT scans may show little or no enhancement or irregular, ringlike enhancement.^{18, 37, 142} Mycotic aneurysms associated with candidiasis have been reported.⁸⁶ Calcification in healed lesions has also been reported.⁶⁶

Nocardiosis

Nocardiosis is an uncommon bacterial disease that has traditionally been included in medical mycology. *Nocardia asteroides* is usually the causative organism. *Nocardia* is found in the soil worldwide. Nocardiosis occurs mostly in immunocompromised patients, patients with diabetes, and those with collagen-vascular disease or preexisting pulmonary disease. The organism is airborne, and the primary focus of infection is usually pulmonary. CNS involvement is usually secondary to hematogenous spread of pulmonary disease, and occurs in about 25% of patients.¹⁵⁷ The most common manifestation is abscess formation, which may be multiple. Pathologically, polymorphonuclear cells are primarily responsible for the inflammatory response. Granuloma formation is rare.

Unenhanced CT scans show low-density areas. MRI studies show low-signal-intensity areas on T1-weighted images and high-signal-intensity areas on T2-weighted images. Contrast-enhanced CT scanning or MRI shows ringlike enhancement, which may be multiple or multiloculated.³⁷

Parasitic Disease Cysticercosis

Cysticercosis is one of the most common parasitic diseases involving the brain. It is caused by ingesting the ova of the pork tapeworm (*Taenia solium*), usually on unwashed, fecally contaminated vegetables or water. The human being serves as the intermediate host of the pork tapeworm, and the main intermediate host of *T. solium* is the pig. By ingesting poorly cooked pork infected with cysticercosis, the human becomes the definitive host for *T.*

Figure 6-29. Mucormycosis. A, T1-weighted sagittal image demonstrates mass effect in the region of the left basal ganglia and thalamus extending into the midbrain with some poorly defined high signal intensity, suggesting hemorrhage (arrow). B, T2-weighted axial image shows a lesion of mixed high and low signal intensity in the left basal ganglia and thalamus with surrounding high-signal-intensity edema. Abnormal high signal intensity is also seen in the right basal ganglia. C, Gadolinium-enhanced coronal image demonstrates an enhancing lesion in the left basal ganglia and thalamus, producing compression and shift of the third ventricle. (From Terk MR, Underwood DJ, Zee CS, et al: MR imaging in rhinocerebral and intracranial mucormycosis with CT and pathologic correlation. *Magn Reson Imaging* 10:81-87, 1992.)

solium. Humans infected with *T. solium* tapeworm excrete eggs of the tapeworm in the fecal material, which then contaminates water and vegetables in areas with poor hygiene. Of course, it is easy for a person with tapeworm in the intestine to become infected with cysticercosis through the anus-finger-mouth route. The disease has been reported to be endemic in parts of Latin America, Eastern Europe, Asia, and Africa. A recent increase in incidence has been noted in the southern and southwestern United States because of immigration.

The intracranial compartment is involved in 60% to 90% of patients with cysticercosis. The location of involvement can be meningobasal, parenchymal, intraventricular, or a combination of these sites.⁹⁵ Parenchymal cysticercosis has a varied appearance on neuroimaging. Following arrival in the brain parenchyma, the precysticercosis embryo transforms into an encysted larva that contains liquid and is covered by a thin membrane. Initially, this cysticercosis

embryo is a living organism, exhibiting morphologic features to signify that it is viable. Similarly, certain morphologic alterations may indicate that the parasite is dead.

Pathologists have identified a series of alterations occurring within and surrounding the larva from its earliest viable stage to its final stage. Escobar,⁴² in providing an interesting account of the disease, has identified four stages that the parasite undergoes within the brain parenchyma.

In the *vesicular stage*, the tiny (4 to 5 mm) live spherical larva appears as a whitish nodule invaginated into a small cyst containing transparent fluid. The cyst has a thin, friable, translucent whitish capsule. The larva can still be found in the colloidal vesicular stage, but it already shows signs of hyalin degeneration and early mineralization. In this stage, the fluid becomes turbid or jelly-like. The capsule steadily thickens with each succeeding phase, so that its walls are noticeably thicker and collagenous by the time the cyst has reached the granular nodule stage. The cyst

Figure 6-30. Parenchymal cysticercosis. *A*, T2-weighted image shows multiple high-signal-intensity lesions. *B*, Gadolinium-enhanced image shows multiple low-signal-intensity lesions with an eccentric isointense scolex. A few of the cysts show partial enhancement of the cyst wall.

reduces its size, and its content changes into coarse granules that are mineralized with calcium salts.

In the *nodular calcified stage*, this granular material appears completely mineralized, with the lesion having shrunk to one half or one quarter of the size of the original live cysticercosis embryo.

On the basis of the preceding data, it seems likely that a cysticercal lesion in the vesicular stage would be identified as such on imaging studies. The cyst fluid would be

isodense to CSF on CT and isointense to CSF on MRI studies. The scolex is isodense to brain parenchyma on CT and hyperintense on MRI studies (Fig. 6-30).

With aging, the parenchymal cysts evolve into the *colloidal vesicular stage*. The cyst wall may show enhancement on contrast-enhanced CT or MRI studies (Fig. 6-31). The cyst fluid may show increased density with CT and intensity with MRI. The scolex begins to degenerate and shrink.

Figure 6-31. Parenchymal cysticercosis. *A*, T2-weighted image shows no definite abnormality. *B*, Gadolinium-enhanced image shows two ringlike enhancing lesions in the right insular cortex.

In the *granular nodular stage*, calcification may be identified within the scolex and along the cyst wall on CT scans. A nodular type of enhancement may be seen on contrast-enhanced CT or MRI. Calcification is much better demonstrated on CT than on MRI.

In the nodular calcified stage, calcification may be seen within the dead larva (Fig. 6-32). Surrounding edema is seen in the colloidal vesicular and granular nodular stages.^{15, 164, 166} Note that evolution of cysticercosis is a dynamic process, and cysts do not change from one stage to another in an abrupt fashion. It is possible to observe cysts in transition from one stage to another.¹⁶³

Intraventricular cysticercosis is potentially lethal; in our series, 6 of 46 patients with intraventricular cysticercosis cysts died of acute obstructive hydrocephalus shortly after hospital admission.¹⁶⁸ The need for early diagnosis of intraventricular cysticercosis cysts cannot be overemphasized. The cysts can be identified by CSF density or signal intensity. Cyst fluid surrounded by a thin wall is a high-density or high-signal-intensity scolex seen on CT or MRI scans (Figs. 6-33 and 6-34). Depending on the stage of the cyst, enhancement of the cyst wall may be identified on the contrast-enhanced CT or MRI study. A thick, ringlike enhancement associated with intraventricular cysticercosis cysts has been correlated with the finding of granular ependymitis in surgical patients (Fig. 6-35). Cysticercosis cysts may migrate within the ventricular system (Fig. 6-36). If time has elapsed since the initial diagnosis, reconfirmation of the location of the intraventricular cysticercosis cyst is advisable before surgery. Metrizamide entrance into an intraventricular cysticercosis cyst has been described.¹⁶⁷

Cysticercosis cysts are seen in the basal cisterns and sylvian fissure. If large enough, these cysts may expand and distort the basal cisterns. MRI studies are more sensitive than CT scans in demonstrating cisternal cysts, which

Figure 6-32. Cysticercosis. Noncontrast CT scan reveals multiple intracranial calcifications, consistent with dead larvae.

tend to agglomerate in a racemose form, and the body or scolex of the parasite is usually not recognizable (Fig. 6-37). It is interesting to consider why cysticercosis cysts present as a racemose form in the basal cisterns. Trelles and coworkers¹⁴⁵ suggested that disordered perforation of the cyst wall is associated with disappearance of the scolex. Martinez⁹¹ held that the racemose cysts are an arrested form in the development of the cyst, the scolex never being formed. Adhesive arachnoiditis develops as a local inflammatory meningeal reaction in the basal cisterns. Contrast-enhanced MRI may show basal meningeal enhancement (Fig. 6-38). Communicating hydrocephalus may also develop as a result of basal arachnoiditis. The inflammatory reaction may involve the adjacent blood vessels and cranial nerves. The walls of the arteries are invaded by inflammatory cells, leading to vasculitis, which can lead to cerebral infarction or mycotic aneurysm formation.¹⁵¹ Spinal cysticercosis cysts can be secondary to intracranial cisternal cysts.¹⁶⁴

Echinococcosis

Hydatid disease, or echinococcosis, is the larval stage of *Echinococcus granulosus*. The definitive host of *E. granulosus* is the dog, and the intermediate hosts are sheep, cattle, and camels. Human infection occurs by accidental ingestion of contaminated dog feces containing ova of a dog tapeworm. The disease is endemic in many sheep-raising and cattle-raising countries in the world.²² Hydatid disease frequently involves the liver and lung. CNS involvement is rare.²⁸ Hydatid cysts of the brain are usually large and spherical, and they may be solitary or multiple.

Extradural cysts have been reported.¹⁰⁶ On unenhanced CT or MRI studies, they appear as large intraparenchymal cystic lesions with sharp margins (Fig. 6-39). Cyst fluid is of CSF density or signal intensity. The lack of surrounding edema is an important feature that serves to differentiate this lesion from cerebral abscess.¹ Contrast enhancement may be seen partially or completely involving the wall. Calcification of the wall may also be seen (Fig. 6-40). Recurrent disease following surgery may present with intense enhancement of the cyst wall and surrounding edema (Fig. 6-41).

Paragonimiasis

Paragonimiasis is the result of infestation by *Paragonimus westermani* in freshwater crabs and crayfish. It is endemic in East and Southeast Asia, West Africa, and Latin America.⁶³ The lungs are the most common site of infestation. Cerebral infection occurs in approximately 1% of patients with pulmonary paragonimiasis.¹⁹

Plain films show characteristic "soap bubble" intracranial calcifications. CT scans show multiple, densely calcified areas with various nodular shapes around and within the lateral ventricles and high over the cerebral convexities.¹⁶⁰

Toxoplasmosis

Toxoplasmosis is caused by infestation with the parasite *Toxoplasma gondii*, a protozoan. The adult form usually

Figure 6-33. Intraventricular cysticercosis. A, T1-weighted image shows multiple cysts in the dependent portions of the lateral ventricles. B, The proton-density-weighted image shows the presence of scolices in some of the cysts better than the T1-weighted image does.

Figure 6-34. Intraventricular cysticercosis. A thin-walled cyst is seen expanding the fourth ventricle. An isointense, eccentrically located scolex is seen.

Figure 6-35. Enhancing intraventricular cysticercosis cyst. *A*, Noncontrast CT scan shows a low-density area in the region of the fourth ventricle. The fourth ventricle is obliterated. *B*, Contrast CT scan demonstrates a ringlike enhancement. (From Zee C, et al: Unusual neuroradiological feature of intracranial cysticercosis. *Radiology* 137:397-407, 1980.)

Figure 6-36. Cyst mobility in cysticercosis. *A*, Initial CT ventriculogram shows a cyst in the third ventricle. *B*, The cyst moved into the fourth ventricle on the metrizamide CT ventriculogram performed on the morning of surgery. (From Zee C, et al: Intraventricular cysticercal cysts: Further neuroradiologic observations and neurosurgical implications. *AJNR Am J Neuroradiol* 5:727-730, 1984. Copyright American Society of Neuroradiology, 1984.)

Figure 6-37. Cisternal cysts and intraventricular cyst. *A*, T2-weighted image shows multiple cisternal cysts in the region of the left sylvian fissure. *B*, Gadolinium-enhanced image shows multiple cisternal cysts in the region of the left sylvian fissure. No enhancement of these cysts is seen in this case. Incidentally, a cyst is seen in the atrium of the left lateral ventricle.

Figure 6-38. Cisternal cyst with basal meningeal enhancement. Gadolinium-enhanced MRI study shows ovoid ringlike enhancement in the pontine cistern and enhancement at the left ambient cistern.

Figure 6-39. Echinococcosis. Large echinococcal cyst is seen in the right temporal lobe in this child. The left temporal horn is dilated. (Courtesy of Dr. Lawrence O'Connor.)

Figure 6-40. Echinococcosis. A and B, Contrast-enhanced CT scans show a large lobulated cyst with marginal calcification (arrow in B) and minimum cyst wall enhancement.

Figure 6-41. Recurrent echinococcosis. A, Gadolinium-enhanced MRI study shows recurrent cysts. No contrast enhancement is seen at this stage. B, Gadolinium-enhanced MRI study obtained a year later shows a decrease in the size of these cysts and contrast enhancement of one of the cysts.

Figure 6-42. Toxoplasmosis. *A*, Noncontrast CT scan shows a large low-density area in the left frontoparietal region and left basal ganglion, with significant mass effect in a patient with acquired immunodeficiency syndrome. *B*, Contrast CT scan demonstrates a ringlike enhancing lesion.

Figure 6-43. Toxoplasmosis. A, T2-weighted image shows a low-signal-intensity lesion in the right cerebral peduncle with surrounding edema. B, Gadolinium-enhanced MRI study shows a ringlike enhancing lesion in the right side of the midbrain.

occurs in immunocompromised patients or in patients with AIDS. Toxoplasmosis may appear as meningoencephalitis or as granulomas. In patients with AIDS, *Toxoplasma* encephalitis is the most common opportunistic infection. The granulomas may be situated at the corticomedullary junction or in the periventricular areas.

Noncontrast CT scans show multiple low-density areas. Contrast CT scans may show no enhancement, nodular enhancement, or ringlike enhancement (Fig. 6-42). MRI

studies are more sensitive in detecting the *Toxoplasma* lesions than contrast-enhanced CT scans.¹⁶⁵ They exhibit hypointensity on T1-weighted images and variable intensity on T2-weighted images. Gadolinium-enhanced MRI studies show enhancing patterns similar to those seen on contrast-enhanced CT scans (Fig. 6-43).¹¹⁴

The differential diagnosis includes lymphoma and progressive multifocal leukoencephalopathy.⁸¹ When treated, healed *Toxoplasma* lesions become calcified. These calci-

Figure 6-44. Neonatal toxoplasmosis. Noncontrast CT scan shows hydrocephalus and scattered intracranial calcifications, with a few seen in the periventricular region.

fications are revealed more effectively by CT than by MRI. In newborns with toxoplasmosis, noncontrast CT scans may show hydrocephalus and scattered calcifications in the parenchyma as well as in the periventricular region (Fig. 6-44). These findings may be seen in cytomegalic inclusion disease, herpes encephalitis, and congenital rubella involving newborns. With cytomegalic inclusion disease, however, calcifications are seen predominantly in the periventricular region.

Various noninvasive methods have been used to differentiate toxoplasmosis and lymphoma in AIDS patients, including SPECT, PET, and MRS. On PET imaging using FDG-18, increased tracer activity is seen in lymphoma as a result of hypermetabolic activity, but it is not seen in toxoplasmosis. On SPECT imaging, thallium 201 uptake also reflects hypermetabolism. On MRS, increased lipid and lactate peaks with a decrease in other metabolites are characteristic for toxoplasmosis (Fig. 6-45). Lymphoma shows a large increase in choline peak with only a mild increase in lipid and lactate peaks. The increased choline peak in lymphoma is believed to be due to increased cell membrane turnover and high cellularity of the lymphoma.¹¹⁷

Stroke

James D. Eastwood

Worldwide, stroke is the second leading cause of death,⁵⁴ and it is the leading cause of permanent disability.⁷ Stroke is also among the most common indications for diagnostic imaging of the brain.

The term *stroke* is most accurately used to describe a clinical event that consists of the sudden onset of neurologic symptoms, and use of the term implies that symptoms are caused by cerebrovascular disease (i.e., a “cerebrovascular accident”). *Cerebral infarction*, by contrast, is a term that describes a lethal tissue-level ischemic event that may or may not cause symptoms. Cerebral infarction accounts for approximately 85% of all strokes.⁴ *Primary* cerebral hemorrhages (e.g., subarachnoid hemorrhage and intraparenchymal hemorrhage) account for most of the remainder.

A number of practical topics are related to clinical imaging of ischemic stroke, and physicians who interpret imaging studies of the brain should be familiar with them. These practical topics form the basis of this chapter.

Etiology of Ischemic Stroke

Ischemic stroke is most often caused by obstruction of cerebral arteries or cerebral veins, although stroke due to obstruction of cerebral *arteries* is substantially more common than stroke due to obstruction of cerebral *veins*. It is useful to consider strokes that are caused by obstruction of *large* cerebral arteries separately from those that are caused by obstruction of *small* cerebral arteries, because the locations and extents of brain tissue involved by these two types of stroke are different. Similarly, the locations and extents of stroke that are caused by obstruction of cerebral veins are generally different than the locations and extents of stroke that are caused by obstruction of cerebral arteries.

In certain situations, cerebral infarction occurring without obstruction of cerebral arteries or veins may also occur, for example, cerebral infarction that is associated with a toxic or an anoxic insult or stroke caused by slow flow, such that seen in patients who experience sustained arterial hypotension. In this chapter, nonocclusive strokes are considered separately from strokes caused by vascular occlusion.

Risk Factors for Stroke

A number of medical conditions are associated with atherosclerotic disease and stroke. Hypertension, smoking, obesity, hyperlipidemia, diabetes mellitus, and homocystinemia are all examples of such conditions that are risk factors for atherosclerosis and stroke.^{14, 43}

Atherosclerosis of the carotid artery is one of the most important conditions that predisposes to stroke.⁶ Indeed, it has been implicated as the etiologic mechanism in approximately one third or more cases of ischemic stroke.⁵⁷ Many types of cardiac disease (e.g., valvular and ischemic heart disease, dysrhythmia, and right-to-left intracardiac shunting of blood) predispose to embolic stroke.⁷⁶ Atrial fibrillation, in particular, causes a substantial number of cardiogenic strokes.²³ Aortic arch atherosclerotic disease is also significantly associated with stroke, presumably as a result of associated thrombotic emboli.²⁷

Many other conditions are often associated with stroke. For example, patients with conditions that predispose to hypercoagulable states, such as those patients with increased levels of factor V Leiden or antiphospholipid antibodies, are at increased risk.^{29, 62} Cerebral ischemia and stroke due to vasospasm are the most important causes of morbidity and mortality in patients with subarachnoid hemorrhage. In addition, about 15% of children with sickle cell disease are afflicted by cerebral infarction.⁵ Stroke may also afflict those with other vasculopathic conditions, such as fibromuscular dysplasia and the vasculopathy associated with neurofibromatosis type 1.

Pathophysiology in Ischemic Stroke

Knowledge of some of the pathophysiologic changes that occur in acute stroke can be helpful to understanding the imaging findings present in patients with acute stroke. Likewise, some of the histopathologic findings that are seen in the first days and weeks after stroke are relevant to an understanding of the imaging findings seen in these patients. A brief discussion of the most essential elements is provided.

Cytotoxic Edema

One concept that is helpful to understanding the changes that are seen in stroke is the development of *cytotoxic edema* associated with ischemia. When regional cerebral blood flow (CBF) falls below about 15 to 18 mL/100 g per minute, electrical activity within human neurons ceases.^{2, 21} With further decreases in CBF (i.e., below about 8 mL/100 g per minute), the associated decrease in availability of oxygen and glucose results in decreased production of adenosine triphosphate (ATP).³⁸ With the loss of ATP production, Na⁺/K⁺ ATPase, an enzyme that is important to cell homeostasis, fails. This event permits the unbalanced influx of extracellular calcium and sodium and, secondarily, the influx of extracellular water into cells. This

increased intracellular water is termed cytotoxic edema. The formation of cytotoxic edema is postulated to be the cause of most of the computed tomography (CT) and magnetic resonance imaging (MRI) findings seen in acute ischemic stroke.

Effects of Cytotoxic Edema on CT and MRI Studies

Because water is lower in density than normal brain tissue, one effect of edema on the appearance of the brain on CT images is a decreased density of brain tissues. This decrease has two primary (albeit related) effects on the appearance of the brain on CT scans (Fig. 7-1):

1. A diminished difference in density that normally exists between gray and white matter. This decrease in contrast may be seen in cortical regions and also at the base of the brain.
2. An overall decreased density in a region of the brain.

Water is also associated with longer T1 and T2 relaxation times than those for normal brain tissue. Therefore, one effect of cytotoxic edema on MRI scans is to increase the T1 and T2 relaxation times of involved tissues. Although regions of the brain that are involved with ischemic stroke may be depicted as areas of relative T1 and T2 prolongation, the changes on a T1-weighted image are not usually seen as early as the changes on T2-weighted images. In the acute stroke patient, the earliest findings on conventional MRI scans are regions of increased signal intensity on long repetition time (TR) images.

Cytotoxic edema can also influence the appearance of brain tissues on imaging studies by creating regional *mass effect*. In acute stroke cases involving the cortex of the brain, stroke-related edema is commonly associated with swelling of the cortical gyri. Gyral swelling is typically identified on imaging studies by the observation that the sulci between the gyri are effaced (i.e., narrowed). Regional sulcal effacement is, therefore, a sign that can be used to detect the changes of acute stroke (see Fig. 7-1).

Mass effect that is associated with acute stroke usually peaks at about 72 hours after the initial ischemic insult, with a gradual decrease in mass effect beginning after that time. When the extent of cerebral infarction is great, the possibility exists that mass effect from brain edema will result in *brain herniation*. Brain herniation represents an important complication of stroke because compression of brain tissues and vascular structures against nonmobile cranial structures (e.g., falx, tentorium, skull base) can result in new neurologic deficits and may exacerbate ischemia and elevate intracranial pressure. Brain herniation can also result in obstruction of cerebral ventricles (i.e., *ventricular trapping*), a problem that also increases intracranial pressure.

When stroke-related edema is extensive and life-threatening, it is sometimes called *malignant brain edema*.⁶⁴ The use of the word *malignant* to describe brain edema associated with stroke should not be confused with the type of brain edema associated with brain neoplasms (i.e., *vasogenic* edema). Life-threatening brain edema that is associated with stroke occurs most commonly in patients with extensive ischemia in the territory of a middle cerebral artery (MCA). Patients with cardiac embolus, internal ca-

Figure 7-1. Acute aphasia and right-sided weakness. *A*, Unenhanced CT scan shows low density, loss of gray matter–white matter contrast, and effacement of sulci within the territory of the left middle cerebral artery. *B*, Maximum intensity projection image (anterior displayed at the bottom of the image) from intracranial 3D time-of-flight MRA shows no signal within the left middle cerebral artery or the left internal carotid artery. The normal appearance of the right internal carotid artery (arrow) and the middle cerebral artery (small arrow) is well visualized by comparison.

rotid artery (ICA) occlusion, and ICA dissection appear to be at highest risk for development of life-threatening brain edema from stroke.⁹ When necessary, control of intracranial pressure may initially be attempted with the use of cerebrospinal fluid (CSF) diversion (e.g., with ventriculostomy catheters). In some cases, severe stroke-related edema may be managed by ipsilateral decompressive craniectomy to reduce intracranial pressure.¹⁸

In addition to the effects on brain CT density, MRI relaxation rates, and local mass effect, the formation of cytotoxic edema may also be related to the changes that are seen on DW magnetic resonance images in acute stroke patients. Such changes may be mediated by an increase in intracellular water with or without a secondary effect on extracellular water diffusion.^{75, 77} DW changes in acute stroke are detailed later (see "Time Course of Diffusion-Weighted Images in Stroke").

T2 Fogging in Late Subacute Infarction

In some patients, during the 3rd week following a stroke, the typical hyperintense signal that is associated with ischemic stroke may regress. In some cases, signal intensity that appears normal may be seen transiently during this period. Such a decrease in signal intensity on a T2-weighted image (T2WI) is called "fogging." The causes of fogging are not clear, but it has been proposed that a decrease in edema, accompanied by increased macrophage activity, may be responsible.^{1, 68} In such cases, parenchymal enhancement on T1-weighted images is typically seen after injection of gadolinium contrast material.

Chronic Stroke

After about 4 weeks, brain tissue that has undergone infarction has completed most of the pathologic changes related to reparation and resorption. Glial scar and areas of cystic necrosis typically have replaced neural tissue. If the volume of infarcted tissue was substantial, there may be evidence of volume loss, such as enlargement of adjacent sulci, cisterns, and ventricles. CT density is typically low, and MRI signal intensities reflect prolonged T1 and T2.

In some cases, areas of gyral increased density and increased signal on T1-weighted images may appear to reflect mineralization (i.e., calcification) within areas of cortical necrosis.⁸ Gyral signal changes may be the most easily identified imaging feature associated with remote infarction, or signal changes associated with chronic stroke may be minimal, with regional volume loss representing the most readily detected evidence of prior ischemia.

Hemorrhage Associated with Cerebral Infarction

Hemorrhage that is associated with ischemic stroke may be symptomatic or asymptomatic. Cerebral hemorrhage that occurs secondary to ischemia is often called a *hemorrhagic infarction* or a *hemorrhagic transformation*. By

comparison, cerebral hemorrhage that is the result of a process other than ischemia (e.g., cerebral hematoma or subarachnoid hemorrhage) can, like ischemic stroke, be associated with abrupt onset of neurologic symptoms. When this occurs, a primary cerebral hemorrhage is sometimes called a *hemorrhagic stroke*.

Because these two types of cerebral hemorrhage that are associated with stroke symptoms have different causes and are often treated differently, the imaging specialist should exercise care when using these terms. Furthermore, the diagnostic investigations undergone by patients with primary hemorrhages of the brain (e.g., MRI, cerebral angiography) are often substantially different from the diagnostic investigations undergone by patients with infarction (e.g., echocardiography, carotid ultrasonography). Because distinguishing primary cerebral hemorrhage from cerebral hemorrhage secondary to ischemic stroke can be of clinical importance, care should be taken to communicate (to the extent possible) whether the primary event appears to be hemorrhage or ischemia.

Evidence that ischemic cerebral hemorrhage is secondary to ischemic stroke is the absence of such hemorrhage on the initial imaging study obtained after the onset of symptoms (Figs. 7-2 and 7-3). Imaging findings suggestive of an ischemic cause of stroke (e.g., dense artery or parenchymal abnormality within a vascular territory) on the initial scan are also helpful. It is typically during the subacute, or reparative, phase (beginning after about 24 hours following the onset of initial symptoms) that hemorrhage may be seen in association with ischemic stroke. By contrast, primary cerebral hemorrhage is typically seen on imaging studies that are obtained at the time of initial symptoms. Primary hemorrhages are discussed in Chapter 16.

Two main forms of hemorrhage may be seen on imaging studies after an ischemic stroke: (1) *petechial* and (2) *space-occupying*.

Petechial hemorrhages are not associated with new mass effect and are often limited to the cortical gray matter. They are thought to be caused by red blood cell diapedesis through small breaches that occur in the endothelium following a stroke (Fig. 7-4).

When greater disruption of blood vessels occurs, space-occupying hemorrhages may occur (see Fig. 7-3). Although the exact cause of these hemorrhages (i.e., hematomas) that occur secondary to ischemic stroke is not certain, it is thought that reperfusion of ischemic tissue, such as may be seen after lysis of a proximal embolus, may be responsible. The use of anticoagulant therapy may also be a risk factor for symptomatic, space-occupying hemorrhage following stroke.

Hemorrhage is also common in stroke caused by venous obstruction. However, the pattern of such hemorrhages often differs from the pattern associated with stroke due to arterial obstruction. In stroke due to venous obstruction, associated hemorrhage is more commonly found in subcortical locations (Fig. 7-5).

On CT scans, the appearance of hemorrhage caused by ischemic stroke is that of increased density. On MRI scans, the appearance of hemorrhage due to ischemic stroke varies with time, but petechial hemorrhages due to ischemic stroke are usually detected as areas of hyperintense signal

Figure 7-2. Hemorrhagic infarction. *A*, Unenhanced axial CT shows low density in the right anterior cerebral artery territory (*arrows*). *B*, Three days later, low density has extended into the middle cerebral artery territory (MCA), and the anterior cerebral artery territory infarct shows evidence of new hemorrhage. *C*, Lateral catheter angiogram shows occlusion of the right internal carotid artery proximally with a small patent stump (*arrow*).

Figure 7-3. Hemorrhagic infarction. *A* and *B*, Unenhanced axial images show low density confined to the deep subcortical regions in this patient with acute left-sided weakness. *C*, Unenhanced CT 2 days later shows extensive hemorrhage within the territory of infarction that has ruptured into the ventricular system.

Figure 7-4. Multiple hemorrhagic infarctions. T1-weighted sagittal image shows several areas of gyral high signal (*arrowheads*) compatible with petechial hemorrhage.

Figure 7-5. Superior sagittal sinus thrombosis. A, T1-weighted sagittal image (unenhanced) shows increased signal in the superior sagittal sinus (*arrows*). B, T2-weighted axial image shows subcortical decreased signal (*black arrows*), surrounded by increased signal edema (*small arrows*). The subcortical location of hemorrhage is characteristic of venous infarction.

on T1-weighted images (see Fig. 7-4), whereas acute hematomas are often depicted as regions of low signal intensity on T2-weighted images (see Fig. 7-5).

Time Course of Contrast Enhancement in Ischemic Stroke

Changes in brain enhancement can be associated with ischemia and infarction. One of the earliest changes in enhancement that can be seen on MRI scans in patients with acute stroke is increased enhancement in the cortical vessels and meninges overlying an ischemic region of the brain (Fig. 7-6). This can be seen in the first hours after onset of symptoms. The precise cause of this increased intravascular enhancement associated with ischemic stroke is not known, but one possibility is delayed wash-out of contrast material due to slow flow. Another possibility is autoregulatory vasodilation. These possible mechanisms would be expected to increase the enhancement seen in vessels by increasing the concentration of contrast material and the size of blood vessels, respectively.

Parenchymal enhancement associated with ischemic stroke, by comparison, is most commonly seen in the subacute time frame and, using standard techniques (i.e., 0.1 mmol/kg gadolinium contrast material and no magnetization transfer pulse), is seen to some degree in most patients by 7 days following an ischemic stroke (Fig. 7-7). Studies have shown that enhancement of the parenchyma can be demonstrated in the acute setting with the use of magnetization transfer (MT) techniques or with high-dose gadolinium injections.⁴⁵ The added clinical value of MT in stroke remains to be determined.

When mass effect and parenchymal enhancement are present in a case of subacute infarction, one must occasionally differentiate infarction from brain neoplasm, such as primary cerebral glioma. Often, simply observing that a given lesion conforms to the expected territory of supply of a cerebral artery (e.g., MCA) can be helpful (see Fig. 7-7). Additionally, apparent diffusion coefficient (ADC) analysis of diffusion-weighted (DW) MR images may also provide evidence of restricted diffusion in a region of enhancement. In such cases, the diagnosis of infarction should be favored. After 5 to 7 days, however, infarction is typically associated with normal to increased ADC values. If clinical suspicion of infarction is high, another MRI scan in 2 to 4 weeks can document decreasing enhancement and mass effect.

Alternatively, magnetic resonance spectroscopy (MRS) can be used to document low *N*-acetyl-aspartate (NAA) peak and increased lactate peak that would be expected in a region of cerebral infarction.^{13, 20} The MRS findings in neoplasms are discussed in Chapter 11. Biopsy should only rarely be necessary to distinguish infarction from tumor. Enhancement due to infarction decreases after 4 to 6 weeks.

CT Versus MRI in the Setting of Acute Stroke

MRI is more sensitive than CT in the setting of acute stroke.⁶⁵ This advantage has increased with the recent clinical

availability of DW MRI. DW MR images have the highest sensitivity and specificity for acute cerebral infarction of any imaging tool presently available.⁶⁶ Nonetheless, CT remains the first imaging test performed at many institutions, even when MRI is subsequently performed. CT is the only imaging test performed in the setting of acute stroke at other institutions. The reasons for this appear to be the high sensitivity of CT for detecting hemorrhage and its greater availability at many institutions.

Small-Artery Stroke

Occlusion of the small end-arteries that penetrate the brain results in focal, deeply located areas of infarction. Such infarctions can be multiple and can occur in the absence of significant disease involving the large arteries. Areas of infarction in the territories of small arteries are frequently called *lacunar* infarctions (Fig. 7-8). It is often assumed that patient histories of hypertension and diabetes mellitus are associated with lacunar infarction more frequently than with other stroke subtypes. However, this concept has recently been challenged.⁵⁸ Locations that are commonly involved with small-artery stroke are as follows:

- Basal ganglia and internal capsule (lenticulostriate arteries)
- Thalamus (thalamoperforate arteries)
- Deep hemispheric white matter (deep cortical perforators)
- Brain stem (pontine perforators and other small brain stem perforating arteries)

Occasionally, a large perivascular space (Virchow-Robin space) may mimic the appearance of a small-artery infarction.²⁵ However, perivascular spaces are most prominent near the surfaces of the brain and have imaging features typical of CSF. A proton-density-weighted image and/or a fluid-attenuated inversion recovery (FLAIR) image can be used to separate infarction (bright) from CSF (dark) (Fig. 7-9).

The imaging specialist can often differentiate infarction in the territory of pontine perforating arteries from other lesions that involve the pons by noting that infarctions in the territories of the paramedian arteries typically have medial margins that approach, but do not cross, the plane of midline (Fig. 7-10). Findings of ischemia that are due to disease involving the small perforating arteries are not limited to lacunar infarctions. Regions of T1 and T2 prolongation (or CT hypodensity) that are larger and less well defined than regions of lacunar infarction may be seen in many elderly patients as well as in patients with a history of hypertension or diabetes. These regions are commonly symmetrical and involve the white matter of the central pons (see Fig. 7-8).

Large-Artery Stroke

Occlusions of large cerebral arteries generally result in regions of ischemic involvement that differ substantially in extent than those produced by occlusion of small cerebral arteries. Nonetheless, it is useful to note that ischemic stroke in the territory of a large cerebral artery may result

Figure 7-6. Acute right-sided weakness. *A*, T1-weighted axial image following intravenous gadolinium (0.1 mmol/kg) shows prominent intravascular enhancement (*arrows*). *B*, T1 postcontrast coronal image shows asymmetrical enhancement of the left tentorium (*small arrows*). *C*, T2-weighted axial image shows high signal in the territory of the left middle cerebral artery (inferior division), consistent with infarction.

Figure 7-7. Enhancing infarction 1 week after symptom onset). *A*, T2-weighted axial image shows increased signal within the cortical territories of the right middle cerebral artery. *B*, T1-weighted axial image following intravenous gadolinium (0.1 mmol/kg) reveals gyral and subcortical enhancement. An enhancing infarct can often be differentiated from tumor by clinical information (e.g., acute onset of symptoms) and extent that conforms to the territory of a cerebral vessel.

Figure 7-8. Acute right hemiparesis. *A*, Fluid-attenuated inversion recovery (FLAIR) MR image (TI = 2000) shows high signal in the periventricular regions (*small arrows*) and posterior limb of the left internal capsule (*arrow*). *B*, Axial diffusion-weighted image (b = 980) shows increased signal only in the left internal capsule, consistent with acute stroke (*arrow*). Other areas that were hyperintense on the FLAIR image presumably represent older ischemic changes.

Figure 7-9. Prominent perivascular space (a potential stroke mimic). *A*, T2-weighted axial image shows a focal area of increased signal in the left base of brain (*arrow*). *B*, T1-weighted image shows the same area to be of diminished signal intensity. *C*, Proton-density-weighted image shows this area to be isointense to cerebrospinal fluid. The location and appearance are typical of a prominent perivascular space (Virchow-Robin space).

Figure 7-10. Acute paramedian perforator infarct. **A**, T2-weighted axial image shows increased signal within the central pons. The medial border of this infarct does not cross the plane of the midline. This tendency to respect the midline is typical of paramedian branch infarction. **B**, Three-dimensional time-of-flight MRA shows no narrowing of the basilar artery in this patient with small-vessel infarction.

in infarctions in the territories of multiple small arteries that receive their supply from the large artery in question. A common example of this phenomenon is the extensive basal ganglia infarctions that may occur in proximal MCA occlusion as a result of loss of supply to the lenticulostriate arteries. Occasionally, the territories of supply of the lenticulostriate arteries may be the only regions that undergo infarction in MCA stroke (Fig. 7-11).

On imaging studies, one feature that can help to differentiate large-artery from small-artery stroke is involvement of cortical gray matter. With large-artery stroke, the earliest changes that are apparent on T2 and proton-density-

weighted images typically are seen in the cortex. As time passes, subcortical hyperintensity becomes more evident and is usually well visualized at 24 hours.

One exception to the rule that cortical findings precede subcortical findings in large-vessel stroke, however, may occur when subcortical low signal intensity accompanies acute cortical hyperintense changes.²² In an animal ischemia model, reversible decreases in T2 relaxation may precede changes on DW scans.¹⁵ An example of subcortical hypointensity associated with a region of presumed ischemia is shown in Figure 7-12.

On occasion, a large-vessel occlusion can result in deep

Figure 7-11. Acute dissection of the internal carotid artery. **A**, T2-weighted axial image shows minimal increased signal within the right basal ganglia (triangles). **B**, Diffusion-weighted ($b = 970$), echo-planar image shows hyperintensity within the same region that is substantially more conspicuous. Diffusion-weighted images have greater sensitivity for acute infarction.

Figure 7-12. Acute left-sided weakness. A, T2-weighted axial image shows extensive subcortical low signal in the right frontal lobe (arrows). B, Unenhanced CT 36 hours later shows development of right frontal hematoma. Hypointense changes on T2-weighted images appear to have preceded hemorrhagic infarction.

subcortical white matter infarction with relative sparing of the cortex. This is presumably a hemodynamic phenomenon caused by a low rate of flow that is not sufficient to supply the territories of the deep perforating arteries (see Fig. 7-3). The terms *internal watershed stroke* and *deep watershed stroke* apply to this pattern of infarction. In such cases, it is the extent of abnormality that helps to distinguish regional subcortical ischemia from other lesions.

Stroke Caused by Internal Carotid Artery Disease

It is thought that diseases resulting in narrowing of the lumen of the ICA can lead to stroke by two likely interrelated mechanisms:

1. *Hemodynamic compromise by obstruction of flow.* Hemodynamic compromise of brain tissues may be minimal when adequate collateral flow is present. Because gradual occlusion of the ICA (e.g., because of atherosclerosis or fibromuscular disease) often allows time for adequate collateral development, gradual occlusion is often clinically better tolerated by patients than sudden occlusion (e.g., acute arterial dissection). Furthermore, in some cases gradual carotid occlusion does not result in neurologic symptoms or brain infarction.
2. *Thrombotic emboli.* In arteries that are irregular or very narrowed, emboli that involve vessels such as the MCA and the anterior cerebral artery (ACA) may be produced.⁷⁸ This concept is supported by diminished stroke rates in patients with carotid artery disease treated with

antiplatelet agents, such as aspirin, as compared with the rates in control patients.¹⁷

The most important disease of carotid arteries that can lead to stroke is atherosclerosis of the ICA (Fig. 7-13). Stenosis due to atherosclerotic plaque most commonly occurs at the level of the carotid bulb. By contrast, stenosis of the carotid artery by fibromuscular dysplasia is more likely to occur distal to the bulb, above the level of the C3 vertebral body.⁷⁰ Type II fibromuscular dysplasia is associated with a characteristic appearance on conventional catheter angiograms consisting of alternating narrowing and dilation, the appearance of which has been likened to a “string of beads.”

Acute dissection of the extracranial cerebral vessels is another relatively common cause of stroke that often occurs following trauma, though some cases occur spontaneously in patients with hypertension or in patients with various arteriopathies (e.g., fibromuscular dysplasia, Ehlers-Danlos syndrome). Patients with dissection of the ICA frequently present with ipsilateral cerebral or retinal symptoms.

Alternatively, patients with carotid dissection may present with ipsilateral Horner’s syndrome, consisting classically of ptosis, miosis, and anhidrosis of the affected eye. Horner’s syndrome due to dissection is thought to be related to disruption of the postganglionic sympathetic plexus that is associated with the cervical carotid artery.

Characteristic locations for cervical arterial dissection include the distal cervical ICA and the cervical loop of the vertebral artery (at the C1 and C2 levels), although other locations may be involved. Vertebral artery injuries, including dissection, may occur in association with cervical spine

Figure 7-13. Atherosclerotic stenosis of the internal carotid artery. *A*, Maximum intensity projection image from 2D time-of-flight MRA shows focal loss of signal ("flow gap") in the proximal left internal carotid artery (arrow), suggestive of flow-limiting stenosis. *B*, Maximum intensity projection image from intracranial 3D time-of-flight MRA shows diminished signal in the left M2 branches (small arrows). The diminished signal is thought to be a result of slow flow and resultant spin saturation.

trauma.⁷⁹ Fractures involving the transverse foramina raise concern for associated vertebral artery injury, including dissection.⁸¹

MRI scans and CT angiograms obtained in patients with extracranial dissection may reveal tapered or irregular narrowing of the affected vessel, with or without evidence of an intimal flap on magnetic resonance angiography (MRA) source images (Figs. 7-14 and 7-15). T1-weighted axial MRI may also reveal hyperintense thrombus within the false lumen of the artery. In cases of suspected dissection, evidence of pseudoaneurysm complicating dissection should be sought. Any evidence of focal outpouching should be confirmed angiographically.

Diseases of the ICA that predispose to embolus formation may result in embolic occlusion of any of the intracranial arteries that receive all or most of their supply from the ICA. Stroke in the territories of the ophthalmic artery, ACA, and MCA are commonly associated with ICA disease.

The anterior choroidal artery also arises from the ICA. It originates at the posterior aspect of the distal ICA, usually just beyond the junction of the ICA with the posterior communicating (PCoM) artery. The territory of the anterior choroidal artery includes several regions that can give rise to focal neurologic symptoms, and occlusion of this artery may produce infarction in the optic tract, cerebral peduncle, and posterior limb of the internal capsule. The anterior choroidal artery is not usually seen directly on MRI or CT scans; instead, it is identified angiographically.

Middle Cerebral Artery Stroke

Stroke in the territory of the MCA is associated with the greatest degree of morbidity and mortality and is among the most common types of ischemic stroke. For the purposes of hyperacute stroke management, a thorough understanding of acute MCA stroke imaging is needed for optimal patient care.

In general, the most important initial goal of acute stroke imaging is to exclude hemorrhage as the cause of new neurologic symptoms. Acute primary intracerebral hematoma and subarachnoid hemorrhage are conditions that represent absolute contraindications to thrombolytic and anticoagulation (e.g., heparin) therapies.

Once hemorrhage has been excluded (typically by CT imaging), the next goals are (1) to help confirm the clinical diagnosis of stroke and (2) to determine the extent of irreversible ischemia. When extensive, irreversible ischemia is associated with a poor prognosis and an increased rate of hemorrhage related to thrombolysis.

Confirming the diagnosis of stroke, by observing the earliest imaging signs associated with stroke and excluding other possible causes of symptoms, can be of value in choosing optimal therapy and minimizing complications.¹⁶

Middle Cerebral Artery Territory

Knowledge of the usual territory of supply of the MCA is essential to understanding the changes seen in acute MCA stroke. The territory of supply of the MCA artery

Figure 7-14. Acute dissection of the internal carotid artery. **A**, Maximum intensity projection image from 3D time-of-flight MRA shows a focal area of irregularity in the distal portion of the cervical segment of the right internal carotid artery (arrow). **B**, Axial “source” image from the same sequence shows diminished signal in the petrous segment of the right internal carotid artery (small arrow). **C**, Unenhanced axial T1-weighted image obtained through the upper neck with fat saturation shows crescentic hyperintense signal representing thrombus (arrow). A small, flow-related signal void represents the residual lumen at this point (arrow-head).

can be considered to consist of a cortical territory and subcortical territory (i.e., that territory supplied by lenticulostriate perforator arteries). The cortical territory of supply of the MCA is reciprocal with that of the posterior cerebral artery (PCA) and the ACA.

The cortical territory of the MCA can be understood to be composed of two main parts: (1) a more anterior part that supplies the frontal lobe and (2) a more posterior part that supplies the parietal and temporal surfaces of the brain.

In common clinical use, the territory of the MCA that is more anterior is said to be supplied by the *superior division* of the MCA; the territory of the MCA that is more posterior is said to be supplied by the *inferior division* of the MCA. This separation of the MCA into two major divisions is based on the proximal branching of the MCA into (usually) two dominant segments. For practical purposes, it is useful to recognize that one main MCA division may become occluded (e.g., by embolus), whereas the other main division remains patent and that the imaging findings of ischemia may reflect this separation.

Substantial variation in territory of supply may occur among patients. Nonetheless, the cortical extent of the

MCA territory may, for practical purposes, be approximated as the insula, the anterior and lateral portions of the temporal lobe, the frontal and parietal opercula, and most of the frontal and parietal convexities. At the level of the ventricles, the MCA territory is approximately delimited by imaginary lines that connect the frontal horns and atria with the cortical surfaces of the frontal and occipitotemporal lobes, respectively. Furthermore, these imaginary lines approximate the hemodynamic watershed zones that lie between the major vascular territories. The concept of a hemodynamic watershed has been proposed to be the basis of a specific type of stroke associated with low flow. So-called watershed strokes are discussed later.

In addition to the cortical branches of the MCA, numerous small perforating arteries originate from the proximal (horizontal) segment of the MCA (the M1 segment). These small arteries are collectively known as the lenticulostriate arteries. Their territories of supply include the basal ganglia, the internal capsule, and portions of the overlying cerebral white matter.

Infarction in the territory of a single lenticulostriate artery results in a lacunar infarct, an event that commonly

Figure 7-15. Acute left internal carotid artery dissection. *A*, Axial T2-weighted image shows extensive infarction in the territory of the left middle cerebral artery. *B*, Axial T2-weighted image through the left of the temporal bone shows abnormal increased signal within the petrous segment of the internal carotid artery (*small arrow*). *C*, Axial "source" image from 3D time-of-flight MRA shows the presence of a low-signal intimal flap (*arrows*) within the upper cervical internal carotid artery. *D*, Unenhanced axial T1-weighted image through the same level reveals a crescentic area of high signal representing thrombus (*arrows*). A small focus of flow-related signal void represents the remaining portion of the lumen.

occurs independently of MCA stroke. Nonetheless, occlusion of the M1 artery typically results in infarction in the territories of multiple lenticulostriate arteries (i.e., striato-capsular infarction). Infarction in the basal ganglia due to MCA occlusion can occur with or without infarction in the territories of the cortical MCA branches (see Fig. 7-11). When occlusion of the MCA occurs distal to the M1 segment (and thus distal to the origins of the lenticulostriate arteries), infarction in the cortical territory of the MCA may occur without infarction of the basal ganglia.

Imaging Findings in Acute Middle Cerebral Artery Stroke

The most important early CT evidence of irreversible brain tissue damage after a hyperacute stroke is hypoden-

sity.⁴⁴ Early CT hypodensity, when extent is greater than or equal to one third of the expected MCA territory, is associated with unfavorable risk of symptomatic hemorrhage following thrombolytic therapy.¹⁶

It is often assumed that changes seen on DW MR scans after a hyperacute stroke reflect irreversible ischemia (i.e., infarction). Although this assumption may be valid in many cases, recent evidence suggests that with human stroke at least some early changes that are depicted on DW images may be reversed following thrombolytic therapy.³⁰ With additional study, criteria may be developed that would allow irreversible ischemia to be reliably distinguished from reversible ischemia, perhaps with the use of DW imaging or DW imaging in combination with another modality, such as perfusion imaging. Because such criteria have not yet been developed and accepted, the following

discussion focuses on the role of early CT imaging in the diagnosis and management of acute MCA stroke.

A number of early CT signs of MCA ischemia have been reported and may be used to confirm clinically suspected stroke of the MCA. One helpful CT sign, when present, is hyperdensity within the MCA.⁵⁹ This finding, in the setting of clinical signs of stroke in the territory of the dense vessel, signifies thrombus within the lumen of the artery (Fig. 7-16). However, a unilateral dense MCA should always be correlated with patient symptoms, since the specificity of this finding alone is not high.⁶³

An important pitfall to avoid is comparing the density of a cerebral artery (e.g., the MCA) with adjacent brain tissue rather than with other vascular structures. The density of the MCA should be compared with that of other vascular structures of similar size, such as the opposite MCA, the ICA, the basilar artery, the large veins, and the dural venous sinuses. Although the hyperdense MCA sign can sometimes assist in the diagnosis of stroke, identification of a hyperdense MCA has some prognostic value and may predict increased morbidity, mortality, and increased risk of life-threatening brain edema.³⁹

Two other helpful early CT signs of acute MCA stroke are obscuration of the lentiform nucleus and loss of the insular ribbon.^{72, 73} These signs are, presumably, the result of ischemia in the territory of the lenticulostriate arteries arising from the M1 segment. The confirmation of these findings, therefore, suggests the presence of proximal occlusion of the MCA. Normally, the insula may be distinguished from the adjacent external capsule by their dif-

fering densities. In early MCA stroke, the contrast between these structures may be lost, presumably as a result of early cytotoxic edema (Fig. 7-17). Decreased density of the basal ganglia, also assumed to be caused by cytotoxic edema, results in obscuration of the lentiform nucleus (see Fig. 7-16).

Although observation of the hyperdense MCA sign, obscuration of the lentiform nucleus, and loss of the insular ribbon signs can help confirm the diagnosis of proximal MCA occlusion, careful examination of the cortical territory of the MCA is also important. Hypodensity, loss of gray matter to white matter contrast, and sulcal effacement should all be sought in the cortical territories. Manual adjustment of the display window and level settings may assist in detecting regions of hypodensity related to early stroke.⁴²

Additional Findings in Chronic Middle Cerebral Artery Stroke

In the chronic stage, infarction in the territory of the MCA (and, to a lesser degree, elsewhere along the corticospinal pathways) may affect the appearance of the brain elsewhere. A common example is wallerian degeneration. When the corticospinal fibers are interrupted, as often happens in MCA stroke, the corticospinal fibers inferior to the lesion may undergo degeneration. The appearance of wallerian degeneration consists of volume loss and increased signal on T2-weighted images (Fig. 7-18).

Another example of change in the appearance of regions

Figure 7-16. Obscuration of the lentiform nucleus. *A*, Unenhanced axial CT scan shows hyperdensity within the proximal (M1) segment of the middle cerebral artery (arrow). *B*, There is decreased density with loss of definition within the left basal ganglia (wavy arrow). Obscuration of the lentiform nucleus and hyperdense middle cerebral artery is one of the earliest signs of stroke on an unenhanced CT scan.

Figure 7-17. Loss of the insular ribbon. Unenhanced axial CT scan in a patient with acute right hemiparesis. There is decreased density with loss of distinction of the insular gray matter from the underlying external capsule (*large arrowheads*). Diminished density is also present in the posterior left temporal lobe (*arrows*). The right insular ribbon appears normal (*wavy arrow*).

Figure 7-18. Wallerian degeneration. **A**, Axial T2-weighted MR image shows the left cerebral peduncle to be of decreased size and increased signal intensity (*arrow*). **B**, T2-weighted image located more superiorly shows evidence of old middle cerebral artery territory infarction. Axonal degeneration is thought to produce the remote subcortical changes.

of the brain outside the territory of ischemia is known as *crossed cerebellar diaschisis*. In general, these changes are seen mainly on hemodynamic (i.e., perfusion) or metabolic studies. In patients with a cerebral injury, diaschisis may be considered to be functional impairment at an anatomic location that is remote from the area that sustained the injury. Diaschisis is thought to occur because of a loss of afferent input to the remote (noninjured) site. In the case of cerebral hemisphere injury, the opposite cerebellar hemisphere may show evidence of decreased blood flow,⁵⁶ decreased blood volume,⁸² and decreased metabolism.⁶⁹ In the case of crossed cerebellar diaschisis, it is thought that the fibers that are interrupted are those within the corticopontocerebellar tract.

Anterior Cerebral Artery Stroke

The territory of the ACA is typically the anterior medial surface of the hemisphere and a small but variable amount of the frontal convexity and inferior frontal lobe (Fig. 7-19). Infarction in the territory of the ACA may occur in isolation (e.g., because of embolus or vasospasm following aneurysm rupture) or in combination with infarction in the territory of the ipsilateral MCA. This latter situation occurs most often with ICA occlusion when the anterior communicating artery (ACoA) is small or absent. Infarction in the territory of Heubner's artery may accompany ACA infarction because the origin of this vessel arises from the ACA in the vicinity of the ACoA. Heubner's artery is a

Figure 7-19. A–C, Subacute stroke of the anterior cerebral artery. Low density and sulcal effacement are present in the medial aspect of the left frontal lobe that extends over the frontal convexity (arrows). A region of subacute infarction is also visible in the right middle cerebral artery territory (curved arrow).

small perforating artery that usually supplies the head of the caudate nucleus and the anterior limb of the internal capsule.

Posterior Cerebral Artery Stroke

The cortical territory of the PCA includes the occipital lobes, the medial and inferior temporal lobes, and the posterior and medial portions of the parietal lobes (Figs. 7-20 and 7-21). The thalamoperforate arteries are small end-arteries that arise from the proximal PCA and the

PCom artery. A consequence of this relationship is that infarction in the territory of the PCA may be associated with lacunar infarctions of the thalamus⁹ (Fig. 7-22). Other small perforating arteries from the proximal PCA supply the cerebral peduncles and upper midbrain.

The PCA usually arises from the basilar artery. Because of this, disease in the vertebral and basilar arteries may result in infarction in the territory of the PCA. However, a common variant of the PCA is an origin from the ICA. In such a case, the vessel is described as having a *fetal origin*. This common variant is associated with severe hypoplasia or absence of the P1 segment (i.e., the segment of the PCA

Figure 7-20. Left posterior cerebral artery stroke. A and B, Low density, visible in the left hippocampus (*large arrows*), is the result of infarction in the territory of the left posterior cerebral artery. A small lacunar infarct is also seen in the pons (*small arrow*). C, Low density is present in the medial left occipital lobe (*arrow*), a finding that is consistent with calcarine artery territory infarction.

Figure 7-21. Infarct of the posterior cerebral artery (parietal-occipital branch). There is a wedge-shaped area of decreased attenuation in the medial portions of the parietal and occipital lobes (*open arrows*). The parietal-occipital sulcus contains the parietal occipital branch of the posterior cerebral artery. The normal location and appearance of the right parietal occipital sulcus are shown (*small solid arrows*).

between the basilar artery and the PCom artery). In patients with this variant, anterior circulation (i.e., carotid) disease can sometimes result in PCA infarction.

Posterior Fossa Stroke

The basilar artery is the sole source of blood supply to the brain stem. Occlusion of the basilar artery is poorly tolerated and can result in rapid progression of ischemic neurologic deficits and infarction (Fig. 7-23). Sometimes collateral supply to the distal basilar artery territory may be present in cases of occlusion of the proximal segment of the basilar artery via retrograde flow from one or both PCAs.

Basilar artery thrombosis can be detected on CT scans by the appearance of hyperdense clot within this artery and variable ischemic hypodensity in the brain stem, cerebellum, thalami, and PCA territory. Careful clinical correlation is recommended when the diagnosis of basilar artery thrombosis is suggested on the basis of unenhanced CT findings, since the appearance of basilar artery thrombosis in some older patients may be mimicked by increased arterial density related to atherosclerotic calcification.

The diagnosis of basilar artery thrombosis may be confirmed with CT angiography or MR angiography, or, more

commonly, with conventional catheter angiography. Basilar artery thrombosis may produce complete or incomplete occlusion of the basilar artery with variable visualization of intraluminal thrombus.

Three arteries provide most of the blood supply to the cerebellum. The posterior inferior cerebellar arteries (PICAs) arise from the intracranial portions of the vertebral arteries. The PICAs supply the posterior-lateral aspects of the medulla, the cerebellar tonsils, and the inferior and posterior surfaces of the cerebellar hemispheres. Occlusion of the proximal PICA can cause infarction of the lateral medulla and tonsil, whereas a more distal occlusion results in infarction mainly along the inferior cerebellar hemisphere (Figs. 7-24 and 7-25).

The anterior inferior cerebellar arteries (AICAs) are usually small vessels that provide reciprocal supply of the cerebellum along with the PICAs. The AICAs are occasionally duplicated and may arise together from a common trunk with the PICA. The AICA gives rise to the artery of the internal auditory canal. Therefore, in addition to causing inferior cerebellar infarction, occlusion of the AICA can result in sensorineural hearing loss, nausea, vertigo, and facial paralysis.

The superior cerebellar arteries (SCAs) arise from the distal basilar artery and supply the superior portions of the cerebellar hemispheres. They often appear duplicated (or triplicated) on angiograms. Infarction of the SCA territory may involve a variable amount of the superior portion of the hemisphere (Fig. 7-26).

The pontine perforator arteries include about 15 to 20 small paired vessels that arise from either side of the basilar artery. Infarction in the paramedian branches of these arteries may result in a centrally located area of abnormal low density or increased signal on long TR images. Infarctions in the territory of paramedian branches of the pontine perforator arteries typically do not cross the plane of midline. This feature can be helpful in the differential diagnosis of deep pontine lesions (see Fig. 7-10). The anterolateral surface of the pons is supplied by the short circumferential branches of the pontine arteries.

An unusual arterial variant whose territory should be recognized is the artery of Percheron.⁴¹ This small artery usually arises from the terminal portion of the basilar artery, then bifurcates to produce two small median thalamoperforate arteries that supply small portions of the medial aspects of both thalami (Fig. 7-27). Knowledge of the territory of supply of this artery, along with the MR appearance of a given lesion, can encourage the imaging specialist to suggest the vascular nature of a lesion in this location.

Infarction Caused by Venous Occlusion

Occlusion of cerebral venous structures may lead to increased intracranial pressure and nonfocal neurologic symptoms, such as headache and seizure, without resulting cerebral infarction. Occlusion of venous structures may also lead to focal cerebral infarction associated with focal or nonfocal neurologic symptoms. Since local cerebral perfusion pressure is related to the difference between local

Figure 7-22. Left posterior cerebral artery (PCA) stroke. *A*, T2-weighted axial image shows increased signal in the left occipital lobe. Focal areas of increased signal are also seen in the left thalamus (arrows). Infarction of the thalamus may accompany PCA stroke as a result of occlusion of thalamoperforate arteries originating from the proximal PCA. *B*, Maximum intensity projection image (viewed from beneath) from 3D time-of-flight MRA. The left PCA is occluded proximally (open arrow). The right PCA has a normal appearance (arrow). The left superior cerebellar artery is visible (arrowheads).

Figure 7-23. Basilar artery thrombosis. *A*, Unenhanced axial CT image shows increased density within the basilar artery (arrow). *B*, Unenhanced axial CT the following day shows extensive cerebellar hypodensity and hydrocephalus due to fourth ventricular and aqueductal compression.

Figure 7-24. Stroke of the posterior inferior cerebellar artery. A and B, Unenhanced CT scan shows well-defined hypodensity in the distal territory of this artery (*arrows*).

Figure 7-25. Bilateral stroke of the posterior inferior cerebellar artery (PICA). A, T2-weighted coronal MR image shows high signal in the territories of this artery bilaterally (*open arrows*). The territories of the anterior inferior cerebellar arteries are spared (*arrows*). B, Axial source image from a 2D time-of-flight MRA study shows diminished signal within both vertebral arteries (*short arrows*). A small channel of flow is present in the right vertebral artery (*long wavy arrow*). The findings are those of bilateral vertebral artery thrombosis.

Figure 7-26. Ataxia in an 8-year-old girl. *A*, Coronal T2-weighted MR image shows a wedge-shaped area of increased signal in the superior left cerebellar hemisphere. *B*, Axial T2-weighted image confirms abnormality in the territory of the superior cerebellar artery. Biopsy showed evidence of evolving infarction.

arterial and venous pressures, the probable mechanism of ischemia in venous infarction is a regional decrease in perfusion pressure that is due to regional elevation of venous pressures.

In most cases, the cause is thrombosis of one or more veins or dural venous sinuses. Cerebral vein and dural sinus thrombosis are often associated with certain predisposing conditions such as dehydration, infection, polycythemia, and sickle cell disease. The presence of a hypercoagulable state also appears to be an important risk factor.^{11, 61} Intracranial venous thrombosis may also occur in the peripartum period³⁷ and may be seen in nonpregnant women taking oral contraceptive medications.

Compared with the location and extent of strokes resulting from arterial occlusion, the location and extent of strokes due to venous occlusion are much more variable. Nonetheless, location and extent of ischemia reflect, to some degree, the location and extent of venous occlusion. For example, when venous occlusion is limited to a cortical vein, findings of infarction may be unilateral and limited in extent to the region of the occluded vein. When venous thrombosis is more extensive, such as when extensive thrombus is present within a major dural sinus structure (e.g., the superior sagittal sinus), the findings of brain ischemia may be bilateral and more extensive. Hemorrhage is frequently associated with venous infarction, although the precise reasons are not known. Furthermore, the hemorrhages that are seen in ischemia as a result of venous occlusion are commonly subcortical in location.²⁸

The imaging signs that are often most helpful for diagnosis of venous occlusion are those that indicate the pres-

ence of thrombus within a venous structure. On CT scans, the presence of hyperdense material within a venous channel and lack of appropriate central enhancement with contrast material are the most important signs (Fig. 7-28). MR images may show increased T1 signal within venous structures occluded by thrombus (see Fig. 7-5). Lack of appropriate flow-related signal void within the venous structure on T2-weighted images and lack of enhancement within the venous structure following injection of gadolinium-containing contrast agents are also typical (Fig. 7-29). Flow-sensitive sequences, such as time-of-flight and phase-contrast MR venograms, can be used to document the presence and extent of venous occlusion.³

A number of pitfalls must be recognized when one is evaluating an MRI scan (including MR venogram studies) for the presence of venous thrombus.³ First, thrombus that is hyperintense on T1-weighted images may be mistaken for flow on time-of-flight images. The imaging specialist can minimize this pitfall by carefully inspecting the unenhanced T1- and T2-weighted images for evidence of clot and by using phase-contrast MR venography alone or in combination with time-of-flight methods. Phase-contrast methods are affected not by the relaxation properties (e.g., T1) of the imaged tissues; they are influenced only by the net displacement (i.e., flow) of spins.

Interpretation of MR scans performed for the evaluation of the dural venous sinuses can also be affected by the fact that flowing blood can appear hyperintense on T1-weighted images, potentially mimicking hyperintense signal due to thrombus. Flowing blood is typically brightest near the edges of the imaged volume, an artifact that can be helpful

Figure 7-27. Cardiac catheterization in a 70-year-old man. *A* and *B*, Axial and coronal MR images show paired bilateral enhancing lesions within the thalami (*arrows*). The appearance and extent are those of subacute infarction in the territory of the artery of Percheron. *C*, Focal enhancement is also apparent in the left occipital lobe (*arrow*). Embolic complications of catheterization frequently involve the posterior circulation.

Figure 7-28. Transverse sinus thrombosis. *A*, Unenhanced axial CT image shows increased density within the right transverse sinus (*small arrows*). The left transverse sinus is of normal density (*larger arrows*). *B*, T1-weighted coronal image following contrast shows absent enhancement in the right transverse sinus (*triangles*).

Figure 7-29. Superior sagittal sinus thrombosis. *A*, T2-weighted sagittal MR image shows increased signal in the superior sagittal sinus (*open arrows*). *B*, Partition image from a phase-contrast MR venogram study (VENC = 5 cm/second) shows regions of absent flow within the superior sagittal sinus (*small arrows*).

in analysis of the findings in a given case. Inspection of the T2-weighted image can also be helpful because absence of signal on long echo-time (TE) images usually suggests that flow is present.

Many patients have congenital absence or hypoplasia of one transverse venous sinus (most often the left), which can mimic occlusion of the sinus on MR venogram studies. In addition, flow gaps within one or both transverse sinuses may be a normal finding in about 30% of patients and should not be mistaken for clot.³ In addition, small papillary arachnoid villi may project into the lumina of dural sinuses and thus may appear as small filling defects that can mimic clot on MR venogram studies. These villi typically appear hyperintense on T2-weighted images, allowing them to be distinguished, in some cases, from thrombus.

Thrombosis of the deep cerebral veins produces a devastating clinical course and characteristic appearance on imaging studies.³⁵ Thrombosis of the internal cerebral veins, the vein of Galen, and the straight sinus may also be accompanied by occlusion of the basal veins (of Rosenthal). Infarction of the thalami, midbrain, and basal ganglia may occur, often associated with hemorrhage (Fig. 7-30).

CT venography is a relatively new but promising modality that provides an alternative to MR venography for the evaluation of the cerebral venous system.⁷⁷ This study is performed with the use of helical acquisition with thin collimation and rapid, continuous infusion of iodinated contrast material. Available commercial postprocessing software can provide surface-shaded renderings and projection-type images of the cerebral venous system. The most important clinical application of this modality is for the investigation of the cerebral venous system for occlusion (Fig. 7-31).

Nonocclusive Stroke and Other Problems

Purely hemodynamic stroke can occur in patients without sources of emboli and with episodic hypotension.⁶ In such cases, the extent of abnormality on imaging studies depends on the degree and duration of systemic hypotension. When hypotension has been relatively mild in degree or short in duration, ischemic changes may be seen in the territories of the watershed zones between major vascular territories or in the deep watershed zones that correspond to the deep cerebral white matter.⁵¹ A parasagittal location, a chainlike pattern, and a deep location all suggest infarction caused by low flow (Fig. 7-32).

Cerebral infarction may also occur in patients who have suffered toxic or anoxic insult. Hypoxemia, carbon monoxide poisoning, and hypoglycemia all have the potential to result in selective or global infarction. Metabolic enzyme and mitochondrial defects can also lead to ischemia and infarction (Fig. 7-33). Selective involvement of the basal ganglia may be seen in many of the processes described. In particular, carbon monoxide poisoning is associated with selective infarction of the globus pallidus, whereas Leigh's disease, a mitochondrial enzyme abnormality, most commonly affects the striatum.⁷⁴ Hypoglycemia can cause a pattern of diffuse ischemia that predominantly affects the parietal and occipital regions.⁵³

Hypoxic-ischemic encephalopathy (HIE) can result in a diffuse or focal infarction in young children and infants (Fig. 7-34). Especially vulnerable are the deep periatlial white matter regions, areas that form part of the deep watershed in infants. On postnatal MRI or CT scans, end-stage periventricular leukomalacia (PVL) is depicted as the symmetrical pattern of periatlial white matter abnormality and volume loss (Fig. 7-35). A number of causes other than hypoxia or ischemia can produce PVL, including infectious and metabolic abnormalities.

Other commonly encountered stroke mechanisms include vasospasm and vasculitis. Following aneurysm rupture, vasospasm of the intracranial arteries is the cause of a substantial part of the morbidity and mortality caused by subarachnoid hemorrhage. Typically, CT or MRI signs of infarction are seen in the territory of arterial insufficiency (Fig. 7-36).

Vasculitis of the cerebral arteries may be primary or secondary to a systemic problem, such as systemic vasculitis or lupus erythematosus. Patients with lupus erythematosus have a particularly high incidence of secondary CNS vasculitis. On CT and MRI studies, the presence of multiple areas of ischemia suggests vasculitis, especially when a substantial number of small cortical and subcortical lesions are present (Fig. 7-37). CT and MRA can depict vasculitic changes in the medium-sized vessels of the circle of Willis; however, visualization of the small cortical arteries is limited with these techniques. Catheter angiography is considered to be the imaging test with the highest degree of sensitivity and specificity for CNS vasculitis.

Cortical laminar necrosis is a histologic, pathologic term that also can be used to describe a particular type of postischemic pattern of injury on CT and MR images. Ischemic injury, occasionally, can be limited to one or more cell layers of the cortex without involvement of the remaining layers. When this occurs, mineralization may develop within the affected layers, producing a gyriform pattern of increased density or signal intensity (on T1-weighted images) (Fig. 7-38).

Diffusion-Weighted Imaging in Acute Stroke

DW images are MR images that are created by applying a pair of magnetic gradient pulses that sensitize the sequence to motion. By applying very large gradients and allowing sufficient time to pass between gradient lobes (pulses), one can sensitize the scan to microscopic motions that are occurring within the imaging voxel.⁴⁸

The amount of diffusion weighting of a DW image is determined by the magnitude of the applied gradients, how long they are switched on, and the time between the two lobes. The magnitude of diffusion weighting is connoted by the "b" value of the image. Typical "b" values (in seconds per square millimeter) for imaging stroke are on the order of 400 to 1000 seconds/mm². By comparing a diffusion-sensitized image (or images) to a similar scan without diffusion-sensitizing gradients (i.e., the "b zero" image), one can compute the amount of diffusion that appears to have occurred.⁴⁰ If this is done on a pixel-by-

Figure 7-30. Deep cerebral venous thrombosis. A–C, Unenhanced axial CT images show extensive low density in the basal ganglia, thalami, and upper brain stem. Foci of hemorrhage are also seen within the brain (*small arrows*). Increased density is seen within the internal cerebral veins, the vein of Galen, and the straight sinus (*larger arrows*). D, T2-weighted MR image 2 hours later shows low signal in the internal cerebral veins (*larger arrows*) and in the vein of Galen and the straight sinus (*small arrows*). Acute thrombus can sometimes appear as low signal, mimicking flow-related signal void. E, Time-of-flight MR venogram shows no signal in the straight sinus (*small arrows*).

Figure 7-31. Superior sagittal sinus thrombosis. Surface-rendered CT venogram study shows absent opacification in the posterior portion of the superior sagittal sinus (*black arrows*). The anterior portion of the superior sagittal sinus is patent (*triangle*). Small cortical veins are depicted (*arrowheads*). The inferior sagittal sinus (*small arrows*) and the vein of Galen are also seen (*open arrow*).

Figure 7-32. Watershed stroke. Intermediate-weighted axial image in a child shows bilateral, symmetrical parasagittal increased signal. The “chainlike” appearance depicted here is often seen with hemodynamic stroke.

Figure 7-33. Leigh's disease in an 18-month-old child. T2-weighted axial image shows increased signal in the basal ganglia bilaterally. Some toxic and anoxic injuries can produce a similar pattern of ischemic injury.

pixel basis, the result is a computed map of apparent diffusion known as an "ADC map."

DW images are highly sensitive to the diffusion restriction that occurs in acute stroke.²⁴ Regions of acute cerebral ischemia are typically hyperintense on DW images and result in diminished ADC values of up to 40%. In experimental stroke models, hyperintensity on DW images can be seen before changes on T2-weighted images are visible.⁴⁹

It is often assumed that hyperintense signal on DW images represents irreversible ischemia. However, studies of experimental stroke and some reports in humans suggest that some changes in diffusion depicted on imaging studies represent potentially reversible ischemia.^{30, 57}

Artifacts on Diffusion-Weighted Images

Acute stroke is characterized by high signal intensity on DW images (Fig. 7-39); however, there are other causes of high signal intensity on these images. Knowing these other causes can be helpful in assessing the likelihood that a given patient has evidence of cerebral ischemia.

One commonly seen artifact that can mimic the appearance of acute stroke is known as *T2 shine-through*. Because DW scans also typically have substantial spin density and T2 weighting, areas of T2 prolongation may result in carryover of hyperintense signal to the DW image. Careful comparison with a reference image (i.e., the "b zero" image) or another type of T2-weighted image can be helpful in recognizing this artifact.

Another artifact that can mimic the appearance of acute stroke on DW images is hyperintensity due to white matter diffusion anisotropy. If one reviews DW images that have

been sensitized to diffusion in only one direction (e.g., the phase-encoding direction), the white matter tracts that run orthogonal to the direction of sensitization appear relatively bright. This artifact can be recognized with experience, although comparison with DW images obtained with the diffusion-sensitizing gradients applied in other directions can also be helpful. One can eliminate this artifact completely by reviewing only images that have isotropic weighting (i.e., DW images that have been combined so that weighting is applied in all three cardinal directions). Such images are also called *trace-weighted* or, simply, *trace* images. Both expressions refer to the diagonal numerical terms that are part of a 3×3 (nine-element) tensor matrix of data that expresses the diffusion properties of an object.⁸⁰

Another artifactual cause of hyperintense signal on DW scans is related to magnetic susceptibility artifacts. Most DW scans are made using *echo-planar imaging* techniques. These very rapid MRI methods are commonly used for DW images because DW scans are highly sensitive to patient motion.

One potential problem with echo-planar images is that they are very sensitive to susceptibility artifacts at soft tissue/bone and soft tissue/air interfaces. Foreign bodies (e.g., shunt catheters) may also produce susceptibility artifacts on DW echo-planar images. Susceptibility artifacts are usually easy to recognize because:

1. They occur in locations (e.g., calvarium and skull base) that are prone to such artifacts.
2. They are often flame-shaped.
3. When severe, they can cause regional anatomic distortion in addition to causing increased signal intensity.

Figure 7-34. Seizure in a 3-month-old girl. *A*, T2-weighted axial image shows areas of cortical and subcortical increased signal involving extensive areas in both hemispheres (*arrows*). *B* and *C*, Axial unenhanced CT scans 12 months later show extensive hypodensity and volume loss involving much of the hemispheric regions bilaterally. The injury was presumed to be hypoxic or ischemic in nature.

Figure 7-35. End-stage periventricular leukomalacia. *A*, T1-weighted sagittal image shows focal thinning of the posterior portion of the body of the corpus callosum (arrows). *B* and *C*, T2-weighted axial images show dilation of the atria of the lateral ventricles and increased signal in the deep periventricular white matter. There are a number of causes of periventricular leukomalacia, one of which is hypoxic-ischemic encephalopathy.

Figure 7-36. Ischemia caused by vasospasm. **A**, Digital subtraction catheter angiogram in a patient with subarachnoid hemorrhage. A ruptured posterior communicating artery-internal carotid artery junction aneurysm is seen (*arrow*). **B**, Unenhanced axial CT image immediately following ligation of the aneurysm shows postoperative changes but no evidence of infarction. **C**, Unenhanced CT 3 days later, after the onset of left-sided weakness, shows new focal hypodensity (*arrows*). **D**, A subsequent angiogram shows significant vasospasm in the right M1 segment (*small arrows*).

Figure 7-37. Vasculitis. Unenhanced axial CT image shows abnormal low density in the basal ganglia bilaterally and in the left frontal lobe (*arrows*). Multiple areas of cortical and subcortical infarction may be seen in patients with vasculitis.

Figure 7-38. Cortical laminar necrosis. A and B, T1-weighted sagittal and axial images show cortical gyral increased signal (*arrowheads*) without substantial volume loss. The extent matches the expected left cortical middle cerebral artery territory. The signal changes are thought to represent mineralization within tissue damaged by ischemia.

Figure 7-39. The patient is a 59-year-old man with acute stroke. **A**, T2-weighted axial image shows increased signal focally within the central (arrow) and lateral (small arrow) portions of the pons. **B**, Axial diffusion-weighted image shows hyperintense signal within the lateral abnormality, suggesting that only this area represents acute infarct. The smaller, central hyperintensity, presumably, represents a more remote ischemic lesion.

Finally, some conditions other than stroke can be associated with diffusion restriction, for example, cerebral abscess.³¹ Cerebral trauma resulting in diffuse axonal injury can also result in foci of hyperintensity on DW scans.^{42a}

Time Course of Diffusion-Weighted Images in Stroke

The very earliest change that can be seen on DW images after an acute stroke is minimal hyperintensity. As mentioned, some early hyperintense changes on DW images may be reversible, both in human stroke patients and in animal subjects. Such findings suggest that separate thresholds of ischemia may exist for early diffusion changes and irreversible cell damage.

ADC values vary with the age of ischemic stroke,⁶⁰ a fact that can influence the analysis of clinical cases. In the first hours after the onset of ischemia, ADC values decrease rapidly, often to 30% or more below normal. ADC values lower than about $60 \times 10^{-4} \text{ mm}^2/\text{second}$ are usually seen in ischemia, and values below $50 \times 10^{-4} \text{ mm}^2/\text{second}$ are often seen. After about 24 hours, ADC values begin to increase again, approaching normal values at about 5 to 7 days. This tendency for ADC values to increase and return to the normal range after the initial decrease that occurs in acute cerebral infarction is termed *pseudonormalization*. After about 2 weeks, ADC values are typically increased within the territory of infarction.

One can often distinguish acute stroke from other diagnoses that are associated with T2 prolongation by measuring diminished brain ADC values within the lesion (i.e., many disease processes are associated with *increased* ADC values). Because ADC values increase with the age of a given infarction, one cannot reliably use ADC measurements to distinguish subacute and chronic infarction from other diagnoses.

Despite these changes in ADC values that occur after a stroke, cerebral infarction on DW images often remains hyperintense throughout most of the time course of stroke. The reason that the appearance of stroke remains hyperintense on DW images throughout its time course is presumably related to T2 shine-through. That is, the fact that the region of infarction is bright on T2-weighted images influences the appearance of the stroke on DW images (which typically have substantial T2 weighting).

In addition to standard DW images and ADC maps, a third type of diffusion image can be created that combines some of the advantages of each. If one divides the DW image by the “b zero” reference image, one can create a calculated image known as the *ratio image*, or *exponential image*.⁴⁷ Such an image is similar to standard DW scans, in that areas of acute ischemia appear hyperintense. Unlike standard DW images, however, so-called exponential images do not have any T2 weighting and thus do not show the effects of T2 shine-through (Fig. 7-40).

Cerebral Perfusion Imaging Hemodynamic Pathophysiology in Cerebral Ischemia

The cerebral perfusion parameters CBF and cerebral blood volume (CBV) are related by the central volume principle, which is expressed as the relation

$$CBF = \frac{CBV}{MTT}$$

where MTT is the mean transit time of a nondiffusible tracer in a volume of brain tissue.³⁴

The pathophysiology of ischemia can be considered in four stages, based on autoregulatory physiology:

Figure 7-40. Diffusion-weighted imaging. Acute right hemiparesis.

A, T2-weighted, echo-planar image without diffusion weighting ($b = 0$). Hyperintense signal is seen in the periventricular regions bilaterally (arrows).

B, Diffusion-weighted image ($b = 1000$) obtained with the direction of sensitization running in the frequency-encoding (front to back) direction. A region of hyperintensity is now seen in the left internal capsule (arrow). Increased signal is also seen in the splenium of the corpus callosum as a result of anisotropy artifact (small arrows).

C, Trace-weighted, diffusion-weighted image ($b = 1000$) shows the lesion in the left internal capsule more clearly (arrow); the anisotropic artifacts seen in the previous image are absent.

D, Exponential diffusion-weighted image. The effect of T2 is removed from the image. The acute infarct is still depicted as hyperintense (large arrow), but the chronic ischemic lesions in the white matter are depicted as areas of diminished signal (small arrows).

E, Apparent diffusion coefficient (ADC) map. The internal capsule lesion (arrow) is depicted as dark (diminished ADC).

F, Quantitative analysis shows that ADC is diminished 37% in the acute infarct compared with a control region.

- *First stage*, normal hemodynamics.
- *Second stage*, characterized by an initial decrease in perfusion pressure. Initially, autoregulatory vasodilation preserves CBF, at the same time increasing CBV. MTT is also typically increased.
- *Third stage*, characterized by greater decrease in perfusion pressure and by an initial decrease in CBF value. CBV typically remains increased.
- *Fourth stage*, characterized by further decrease in perfusion pressure and decreases in both CBF and CBV. This stage is associated with tissue ischemia and hemodynamic failure.

Perfusion Imaging in Stroke

An important goal of hemodynamic stroke imaging is the depiction of tissue at risk for infarction that might be saved through intervention. In the setting of acute stroke, if the location and extent of viable tissue at risk for infarction were known, such knowledge could help clinicians to weigh the risks associated with stroke therapies. Viable tissue that is at risk for infarction is commonly called the *ischemic penumbra*, or the tissue outside the (nonviable) core of infarction that is nonetheless underperfused. It is postulated that the ischemic penumbra differs from viable tissue that is not at risk by the (decreased) amount of blood flow that it receives.

A number of methods of imaging cerebral perfusion are available. Imaging with radioisotopes is possible with single-photon emission computed tomography (SPECT) and

positron emission tomography (PET). It is also possible to image CBF with CT using inhaled stable xenon.¹⁰ This method is capable of depicting extent of hemodynamic abnormality in stroke.⁷¹ Although xenon CT remains an attractive tool for the assessment of CBF, this method has not yet achieved widespread clinical use. One possible reason may be the requirement for specialized equipment to administer and ventilate the gas.

It is now possible to obtain dynamic, contrast-enhanced perfusion scans using either CT or MR scanners^{32, 66} (Figs. 7-41 and 7-42). Generally, a volume of contrast material is injected rapidly into an arm vein by an automatic (power) injector, and the bolus of contrast material is tracked by the scanner through a slice or slab of brain tissue that is repeatedly scanned over the course of about 45 to 60 seconds. For best results, temporal resolution of 2 seconds or faster is needed.

It has been proposed that MR perfusion imaging may complement DW imaging in depicting the region of penumbra.²⁶ The premise is that DW imaging is thought to depict the region of core infarction, whereas the region of perfusion abnormality represents both the core and the penumbra. The difference between the extent of the diffusion abnormality and the extent of perfusion abnormality is thus thought to represent penumbra.

An alternate approach for determining the extent of penumbra is to use perfusion maps alone to distinguish the core of infarction from the penumbra, usually with the use of perfusion parameter value thresholds. The most commonly used perfusion parameter is the mean CBF value. Earlier work with xenon CT in stroke patients has

Figure 7-41. Acute stroke of the right middle cerebral artery. A, Unenhanced axial CT scan of the brain shows no substantial abnormalities. B, Mean transit time (MTT) map from dynamic CT perfusion scan depicts a well-defined region of MTT prolongation. The extent and degree of regional hemodynamic abnormalities can be determined by perfusion imaging techniques.

Figure 7-42. Acute dissection of the right internal carotid artery. *A*, Trace-weighted, diffusion-weighted image ($b = 1000$) shows cortically based region of hyperintense signal consistent with acute middle cerebral artery territory infarction (arrow). *B*, Negative enhancement integral image (relative cerebral blood volume) from gadolinium-enhanced dynamic sequence. The extent of a region of (arrow) diminished perfusion is identical to the diffusion-weighted image abnormality (arrow). This represents a “matched” perfusion and diffusion defect.

described thresholds for infarct core (CBF values < 7 mL/100 g per minute) and penumbra (CBF values between 7 and 20 mL/100 g per minute).¹⁸

The perfusion parameter CBV may provide additional information about tissue viability that CBF alone cannot provide. Studies using MRI with SPECT and xenon CT with dynamic CT have shown that for tissues associated with moderately low CBF values, CBV value can help to predict tissue viability.³⁰ These studies suggest that moderately decreased CBF values and increased CBV values may carry a better prognosis than that for tissues in which both CBF and CBV values are diminished.

Cerebral Aneurysms and Vascular Malformations

Theodore C. Larson III

Cerebral Aneurysms

Incidence and Natural History

Cerebral aneurysms are found in approximately 0.5 to 5% of the population.^{130a, 139, 193, 242, 255, 261, 262, 326, 339a} Women have a variably greater incidence of cerebral aneurysms compared with men, and aneurysm development increases with advancing age.^{15, 139, 242, 297, 326} Some families demonstrate a genetic predisposition to develop cerebral aneurysms.^{43, 214, 305} The risk of new aneurysm development is approximately 2% per year.¹³⁹ Subarachnoid hemorrhage, the most common presenting symptom of a cerebral aneurysm, is the second most common cause of subarachnoid hemorrhage, after trauma.²⁶¹ Eighty percent to 90% of nontraumatic subarachnoid hemorrhages are due to a ruptured cerebral aneurysm, a far more common cause than an arteriovenous malformation, which accounts for 15% of subarachnoid hemorrhages.³⁰¹ Other, less common presenting signs and symptoms, which are due to mass effect or neighboring inflammation, aneurysm thrombosis, or aneurysm-generated emboli, are cranial nerve palsy, headache, seizure, and transient or permanent neurologic dysfunction.²⁴² These nonhemorrhagic symptoms can be seen with aneurysms of any size but occur more commonly with posterior circulation or internal carotid aneurysms.²⁴²

The annual incidence of rupture of an asymptomatic cerebral aneurysm has been estimated at approximately 0.5% to 2%, or roughly 10 cases per 100,000 population.^{135, 139, 255, 273, 326} Symptomatic intact aneurysms have a higher rate of bleeding—4% or more per year. Some studies have suggested that for aneurysms less than 1 cm in diameter, the incidence of annual rupture is less than 0.1%.^{315a, 326} Other reports, however, have documented that the majority of ruptured aneurysms are less than 9 to 10 mm in diameter,^{130a, 141, 255} and that even small (2 to 3 mm) aneurysms may cause subarachnoid hemorrhage.^{10a, 273, 288, 340} The presence of a daughter sac probably raises the likelihood of rupture.^{273, 326} Younger patients may have a greater propensity for aneurysmal hemorrhage, especially if they have multiple aneurysms.¹³⁹

A ruptured cerebral aneurysm carries significant morbidity and mortality, the 30-day mortality traditionally being stated as 40% to 60%.^{139, 141, 255, 262} Untreated patients with ruptured cerebral aneurysms have a rebleeding rate of 10% to 50% in the first 2 weeks to 6 months. The rebleeding rate is highest in the first day, with a 50% mortality.^{5, 40a, 135,}

^{141, 231a, 236a, 297}; thereafter, the bleeding rate is approximately 3% per year.^{135, 139} Initial aneurysm size is not a prognostic factor influencing rebleeding in the acute period.¹⁴¹ Approximately 14% to 23% of survivors of rupture of a cerebral aneurysm are left with significant morbidity^{255, 267}; in 13% to 32% of cases, the morbidity is the direct result of delayed vasospasm-caused ischemia.^{193, 231a, 236a, 267} Twenty-one percent of patients who enter the hospital for treatment of subarachnoid hemorrhage eventually die.²⁶⁷ Surgical clipping of acutely ruptured aneurysms results in improved functional outcome compared with delayed intervention.²¹⁸ These data also argue for elective treatment of an unruptured aneurysm.

Unruptured cerebral aneurysms are most often asymptomatic but can cause local mass effect and headache. Focal mass effect can compress adjacent cranial nerves or brain parenchyma, a typical example being third nerve palsy due to a posterior communicating aneurysm. Other diseases can cause neurologic deficits similar to those due to aneurysms, however. For example, third nerve palsy could be caused by diabetes or microvascular disease instead of a posterior communicating aneurysm. When magnetic resonance imaging (MRI) and MR angiography (MRA) fail to diagnose the cause of the patient's third nerve palsy, catheter cerebral angiography may be required to exclude a cerebral aneurysm, because the morbidity and mortality associated with cerebral aneurysms are so significant. When catheter cerebral angiography does not demonstrate an aneurysm in a patient with no history of subarachnoid hemorrhage, the patient can be assumed to have small-vessel cerebrovascular disease. Sometimes the angiogram supports this diagnosis by showing other areas of atherosclerotic disease.

Types of Aneurysms, Etiology, and Pathology

Aneurysms may be divided into different classifications according to morphology, size, location, or etiology. Most cerebral aneurysms are acquired lesions and are saccular or fusiform. Older medical reports proposed that saccular or berry cerebral aneurysms were due to an embryologic abnormality of the walls of cerebral vessels.²²¹ Stehbens²⁹³ and others have refuted this theory. Most cerebral aneurysms develop from hemodynamic stresses,^{143a, 262, 293} which typically occur at vessel bifurcations or terminations, or

along the outer curvature of looping vessels.^{143a, 197, 244, 273, 293} The aneurysm's location is a continuation of the primary flow direction in the parent vessel, especially if the parent vessel is tortuous.²⁴⁴ Rupture and thrombosis of cerebral aneurysms are also believed to be due to hemodynamic forces.^{97, 293} Supporting this theory of an underlying etiology is the higher incidence of cerebral aneurysms in patients with intracranial vascular anomalies, including fenestrations and congenital or iatrogenic vascular variants of the circle of Willis (e.g., persistent trigeminal artery, unilateral absence of the A1 segment of an anterior cerebral artery, azygous proximal anterior cerebral artery, and occlusion or absence of an internal carotid artery).^{205, 236, 264, 272} Primary causes of aneurysms are as follows: (1) atherosclerosis, (2) hypertension, (3) smoking, (4) abuse of cocaine, methamphetamine, ephedrine, heroin, and other drugs with resultant arteritis or hypertension,^{132, 139, 206, 230} (5) vascular malformations (approximately 6% to 10% incidence of aneurysm, both proximal flow-related and nidus^{11, 44, 60, 90, 148, 186, 204}), (6) specific vascular diseases, such as fibromuscular dysplasia (20% to 50% incidence of aneurysm^{113, 272}), spontaneous cervical carotid or vertebral artery dissection (more commonly seen in women²⁷²), Takayasu's arteritis,¹¹¹ polycystic kidney disease (10% incidence of aneurysm), and neurofibromatosis,¹¹⁷ and (7) the connective tissue disorders, such as Marfan's syndrome and Ehlers-Danlos syndrome (in which aneurysms of the carotid siphon to supraclinoid segment are more common).²⁷² The walls of saccular cerebral aneurysms contain intima and adventitia but the media and internal elastic membrane are thinned or absent.^{49, 50}

A number of patients with cerebral aneurysms demonstrate collagen type III abnormalities.²⁷² Most cerebral aneurysms arise from the circle of Willis and middle cerebral artery bifurcations. Ninety percent involve the anterior circulation, and 10% the posterior circulation.^{11, 221} The most common sites are the anterior communicating artery at its junction with the adjacent anterior cerebral artery (30% to 35%), the posterior communicating artery at its union with the internal carotid artery (30% to 35%), the middle cerebral artery bifurcation (20% to 25%), the basilar terminus (5%), the carotid terminus (5%), and the origin of the ophthalmic artery (5%).²²⁷ Less commonly, aneurysms occur along the course of the anterior cerebral arteries, particularly at the origin of the callosomarginal artery, the middle cerebral arteries, posterior cerebral arteries, superior cerebellar arteries, anterior inferior cerebellar arteries, and posterior inferior cerebellar arteries.^{15, 115, 130a, 244, 259}

In 15% to 30% of patients, multiple aneurysms are found, more often in women than in men by a 5:1 ratio,^{139, 141, 297, 297a, 307a, 316} and most frequently involving the middle cerebral artery.³⁴⁰ Of the patients with multiple cerebral aneurysms, 75% have two, 15% have three, and 10% have four or more.²⁹⁷ When one of multiple aneurysms ruptures and causes subarachnoid hemorrhage, it is most often the largest³⁴⁰ although this is not always the case. For instance, Nehls and colleagues²⁰⁹ have reported the propensity for anterior communicating aneurysms to rupture when several are present simultaneously. Vasculopathies, such as fibromuscular dysplasia and connective tissue disorders, as well as syndromes such as polycystic kidney disease are associated with a higher incidence of multiple cerebral aneurysms. Bilateral symmetrical aneurysms are called *mirror*

aneurysms, and they most often involve the internal carotid arteries or the middle cerebral artery bifurcations.²⁹⁷

Other causes of cerebral aneurysms, identified in less than 5% of patients, are (1) penetrating and nonpenetrating trauma, (2) dissection (post-traumatic or otherwise), (3) inflammation or mycosis due either to septic emboli causing destruction of the endothelium or to spread of infection to the vasa vasorum with subsequent vessel wall destruction and focal dilatation, and (4) neoplasm; rarely, cerebral aneurysms may be congenital.^{5, 139, 161, 170, 212} Except for congenital aneurysms, aneurysms with these uncommon causes often develop in unusual locations that are distal to the circle of Willis.

Trauma typically results in a pseudoaneurysm rather than a true aneurysm, because no normal vascular components constitute the sac within a hematoma that communicates with the injured vessel. Post-traumatic pseudoaneurysms occur in locations not common for other cerebral aneurysms, including the proximal internal carotid artery, particularly at the skull base²⁸⁰; the meningeal vessels, which often are associated with overlying skull fractures and epidural hematomas³¹¹; the posterior cerebral or anterior cerebral arteries, caused by tentorial or falx impaction, respectively^{170, 205, 212, 280}; and in extracranial vessels within the scalp, such as the superficial temporal artery and the occipital artery.²⁸¹ Penetrating, high-velocity trauma, such as from gunshot wounds, is more likely to produce a traumatic aneurysm if the entrance site is in the temporal or peritemporal region, if fragments cross the midline, and if the pseudoaneurysm is surrounded by hematoma. The surrounding anterior and middle cerebral arteries are most often involved.⁹ Initially, traumatic pseudoaneurysms may not be visualized, but then they rapidly enlarge.^{205, 280} Fifty percent of untreated, post-traumatic aneurysms bleed, with an almost uniformly fatal outcome.^{9, 205}

Uncommon neoplastic aneurysms are also pseudoaneurysms, resulting from primary or metastatic tumor invasion of a vessel or metastatic emboli to the vessel lumen or its vasa vasorum.^{92, 116a} **Pituitary adenomas** are associated with a higher incidence of cerebral aneurysms, acromegaly-producing adenomas theorized to sometimes produce diffuse cerebrovascular ectasia and unilateral or bilateral cavernous carotid aneurysms due to growth hormone secretion.^{11, 327}

Dissection of the internal carotid artery or more commonly the vertebral artery can be spontaneous, post-traumatic, or secondary to disease of the vessel wall such as fibromuscular dysplasia.^{200a} A pseudoaneurysm accompanies up to a third of internal carotid dissections and 7% of vertebral artery dissections.^{5, 289} Dissecting pseudoaneurysms may manifest as ischemic symptoms due to emboli or small arterial branch occlusion in addition to subarachnoid hemorrhage.⁵ Dissecting pseudoaneurysms more commonly present as subarachnoid hemorrhage when occurring in the posterior circulation.^{85a} Rebleed rates are particularly high with accompanying significant mortality.^{200a}

Fusiform aneurysms are vascular ectasias due to advanced focal atherosclerotic disease that has degraded the vessel's media.^{5, 293} The vertebrobasilar system is more commonly affected than the anterior circulation. The involved vessel is frequently elongated and tortuous, so that

in effect, the native vessel is replaced by aneurysmal dilatation with no neck. Although fusiform aneurysms may rupture, thrombosis due to blood stagnation may be the mode of presentation. Local mass effect, ischemia due to penetrating vessel occlusion, and cranial nerve palsies are other pathologic sequelae.^{5, 302}

An infundibulum represents the residua of a developmental vessel that has undergone incomplete regression. It most commonly involves the junction of the internal carotid artery and posterior communicating artery, and less commonly the origin of the anterior choroidal artery from the internal carotid artery. Infundibula are usually 3 mm or less in diameter. They can be difficult to differentiate from cerebral aneurysms unless the characteristic origination of the emerging vessel from the dome of the infundibulum is identified.

Imaging Evaluation of Cerebral Aneurysms

Imaging objectives for the identification of a cerebral aneurysm are (1) visualization of subarachnoid hemorrhage, (2) confirmation of the size, location, and morphology of the cerebral aneurysm, (3) evaluation of the adjacent cerebral vasculature, including evidence of spasm, atherosclerosis, displacement, and incorporation into the aneurysm's wall, and (4) demonstration of any accompanying adjacent brain pathology.

The typical patient with a ruptured cerebral aneurysm is a woman between 40 and 60 years old who presents with "the worst headache of my life," with or without a neurologic deficit. Clinical assessment of the patient classifies into Hunt and Hess grades I through V (Table 8-1).^{124a} CT scan of the head identifies subarachnoid hemorrhage, and the patient undergoes catheter angiography, which is timed to precede surgical treatment with either craniotomy or endovascular coiling. In patients in whom CT scan shows no hemorrhage, lumbar puncture should be performed. Patients with a positive lumbar puncture result then undergo catheter cerebral angiography, unless the lumbar tap was traumatic. In some situations, MRI and MRA may be performed to evaluate the subarachnoid hemorrhage and to identify a cerebral aneurysm, for example, when the suspicion for a cerebral aneurysm is low or the patient is a poor candidate for cerebral angiography or aneurysm intervention (i.e., is elderly or severely injured). MRI and MRA may also be employed as screening tests in populations known to have a higher incidence of cerebral aneurysms (see preceding discussion) or for monitoring known, untreated aneurysms. Although the permanent neurologic risk

of catheter cerebral angiography is low—approximately 0.8% in the usual patient population with ruptured cerebral aneurysms—one should always keep in mind the morbidity of stroke when deciding whether a particular patient should undergo the procedure.

Computed Tomography

The most important role for CT in the patient with a cerebral aneurysm is in the identification of acute subarachnoid hemorrhage, which is demonstrated as increased density within a cisternal space (Fig. 8-1). The location of the subarachnoid hemorrhage may help determine the location of the underlying cerebral aneurysm.^{1, 5, 259, 277, 297} For example, blood in the sylvian fissure most likely has arisen from a middle cerebral aneurysm, and blood in the fourth ventricle is a common sign of rupture of a posterior inferior cerebellar artery aneurysm.²⁵⁹ Some subarachnoid hemorrhage patterns are not diagnostic of aneurysm location, and none is foolproof.

The CT demonstration of subarachnoid hemorrhage progressively decreases until it disappears by approximately 3 weeks,^{107, 259} depending on the initial amount of subarachnoid hemorrhage. In 5% to 10% of CT scans, subarachnoid hemorrhage is not identifiable. For this reason, any patient in whom acute subarachnoid hemorrhage is suspected but CT scanning does not demonstrate intracranial blood should undergo lumbar puncture.

A small amount of aneurysmal subarachnoid hemorrhage adjacent to the brain stem may be mistaken for perimesencephalic (prepontine and interpeduncular) hemorrhage, a finding believed to be due to the rupture of small perimesencephalic veins^{139a, 248} and usually resulting in a good outcome, unlike an aneurysm rupture.

TABLE 8-1. Hunt and Hess Grading Scale for Subarachnoid Hemorrhage

Grade I	Asymptomatic or minimal headache
Grade II	Moderate to severe headache, nuchal rigidity, oculomotor palsy, normal level of consciousness
Grade III	Confusion, drowsiness, mild focal neurologic deficit
Grade IV	Stupor or hemiparesis
Grade V	Comatose or moribund with decerebrate posturing

Fig. 8-1. CT demonstrating subarachnoid hemorrhage (arrow) from aneurysm rupture.

CT is also excellent for identifying intraventricular hemorrhage (seen in 13% to 28% of cases²⁵⁹), parenchymal hematoma (20% to 30%), and the occasional subdural hematoma, findings that often help localize the underlying aneurysm.

CT examination is secondarily important to identify cerebral aneurysms, typically 5 mm or larger in diameter. The rate of identification of cerebral aneurysms by thin-section, high-resolution, contrast-enhanced CT scanning has been reported to be at least 67% for aneurysms 3 to 5 mm in diameter and to approach 100% for larger aneurysms.^{271, 274} Focal, slightly dense areas of luminal blood in

typical locations where aneurysms arise,³⁴² focal globular or elongated areas of contrast enhancement,²¹⁰ variable calcification involving the aneurysm's walls, and clot within larger aneurysms characterize cerebral aneurysms.¹⁰⁸ Large aneurysms have a transverse dome diameter of 1.0 to 2.4 cm, and giant aneurysms are 2.5 cm or more in diameter. Large and giant cerebral aneurysms are typically more easily identifiable because of their conspicuous size but also often from the presence of internal clot and peripheral wall calcifications, especially in giant aneurysms (Fig. 8-2). Giant aneurysms are most commonly identified in middle-aged women, are typically located in the extradural

Fig. 8-2. CT examination demonstrating calcification and old thrombus within a giant anterior communicating aneurysm. A, CT scan without contrast documenting calcification within the aneurysm's wall (arrow). B, CT study with contrast demonstrating the contrast-enhancing patent lumen (short arrow) and the majority of the aneurysm filled with thrombus (long arrow). C, AP view of the right carotid angiogram illustrating the patent portion of the anterior communicating aneurysm (arrow) that is much smaller than its total volume.

carotid artery, the middle cerebral artery bifurcation, or the basilar summit, and usually manifest with a mass effect but can present as subarachnoid hemorrhage.^{48, 69, 141} Any large aneurysm can have a mass effect on adjacent brain or cranial nerves. CT is excellent for identifying skull base erosion due to large or giant aneurysms, especially if thin sections (3 mm or less) are obtained.

Brain parenchymal hemorrhage, which may be associated with any of the cerebral aneurysms, is thought to occur from acute or chronic rupture of the cerebral aneurysm into adjacent brain substance after the blood passes through overlying pia. Both parenchymal and subarachnoid hemorrhages often obscure an underlying ruptured cerebral aneurysm.

MRI

The identification of acute subarachnoid hemorrhage by routine MRI has been notoriously poor,^{19, 217} although there are reports that claim otherwise.¹³⁶ The following two reasons have been postulated for the lack of visualization of acute subarachnoid hemorrhage on MRI¹⁰⁴ (1) normal P_{O_2} (partial pressure of oxygen) in CSF inhibits the development of deoxyhemoglobin and (2) lysis of red blood cells in subarachnoid CSF prevents heterogenous magnetic susceptibility. However, with the employment of pulse sequences including intermediate-weighted spin-echo with TE (echo time) values of 22 to 45 msec, T1 weighting, FLAIR (fluid-attenuated inversion recovery) imaging, and gradient-echo imaging, acute subarachnoid hemorrhage can frequently be identified. Other imaging problems can obscure precise identification of subarachnoid hemorrhage on MRI, including CSF and vascular pulsation artifact and magnetic susceptibility artifact along the skull base. Significant experience is therefore required to correctly identify acute subarachnoid hemorrhage on MRI. Subarachnoid hemorrhage older than 12 to 24 hours can routinely be identified on MR images, often helping pinpoint the underlying ruptured cerebral aneurysm by a collection of blood.

Thin-section MRI examination can often identify cerebral aneurysms more than 3 mm in diameter.¹⁹⁷ The identification may be easier if the aneurysm is unruptured. It may be difficult, however, to differentiate normal vascular tortuous anatomy or bone such as the anterior clinoid process from a cerebral aneurysm. When large enough, cerebral aneurysms can be positively identified on MRI as flow artifacts or characteristic findings with the use of different pulse sequences. Phase-encoding artifact due to flow-producing signal mismatched in the phase-encoding direction is optimally seen on the short TE, long TR, spin-echo pulse sequence, which may be the best sequence for positive identification of aneurysms (Fig. 8-3). Other flow effects, such as a swirling appearance inside the aneurysm due to spin dephasing, rephasing, and turbulence, even-echo or gradient rephasing, diastolic pseudogating, slow flow, variable intraluminal flow rates, entry slice enhancement, and signal void due to rapidly flowing blood on all pulse sequences except those using short TE, short TR, relatively large flip angle gradient echo scans that are typically employed for time-of-flight (TOF) MRA studies, are often also helpful to identify cerebral aneurysms.^{12, 39, 252a, 321}

Contrast enhancement of the aneurysm highlights its central lumen and can exaggerate the aforementioned artifacts, particularly the phase mismatching effects. For instance, these clues can often reliably diagnose cavernous carotid segment aneurysms and differentiate them from pituitary masses. A partially thrombosed aneurysm contains peripheral layers of clot of different ages, usually with the oldest clot located most peripherally.^{13, 108, 302} MRI may identify intramural thrombus in dissecting aneurysms, aiding in their distinction from fusiform aneurysms.⁵ The signal intensities of intraluminal clot correspond to the expected age of hemorrhage on MRI according to the magnetic field strength employed.^{13, 108} Fibrosis and cellular infiltration can accompany the clot.

Completely thrombosed aneurysms or aneurysms with extremely slow flow can rarely mimic tumors, including sellar and parasellar masses. Catheter cerebral angiography should be undertaken in these problematic cases, to prevent "surprises" during craniotomy and potentially catastrophic hemorrhage during trans-sphenoidal or other operations.

The brain parenchymal changes adjacent to cerebral aneurysms may be absent unless the aneurysm is large enough to cause edema and localized mass effect. MRI is superior for evaluating the relationship of the aneurysm with adjacent brain structures because of the inherent soft tissue contrast limitations to and posterior fossa beam-hardening artifact seen with CT. If the aneurysm has ruptured, an adjacent intraparenchymal or subarachnoid clot may be identified. This finding is especially useful for determining which aneurysm has ruptured in a patient with multiple aneurysms, especially when clinical localizing signs are not helpful.^{107, 297} The imaging location of the clot can subsequently guide treatment.¹⁰⁷ Chronic changes include gliosis and deposition of hemosiderin or ferritin; the latter two substances represent hemorrhagic breakdown products, which are best demonstrated on long TE, long TR, T2-weighted spin-echo or T2* gradient-echo MRI sequences. Superficial siderosis represents intracellular (most often macrophage) and extracellular hemosiderin or ferritin coating the leptomeninges, cranial nerves, and superficial central nervous system parenchyma.⁹⁵ The siderosis is secondary to any cause of subarachnoid hemorrhage, usually repetitive, but can also occur on the ventricular ependymal surfaces.⁹⁵ Focal or generalized neurologic deficits correspond to the location and extent of central nervous system involvement.⁹⁵

MRI is superior to CT for the localization of cerebral aneurysms, their relationship with adjacent structures, and associated changes in neighboring brain tissue.

MRA and CT Angiography

MRA has made tremendous strides in the identification of cerebral aneurysms. Between 55% and 86% of cerebral aneurysms may be identified with routinely available MRA.^{17, 128a, 240, 256, 275} Sensitivity of MRA for detection of aneurysms can be increased when MRA is combined with MRI,^{256, 275} thereby overcoming the inherent difficulties of imaging slow flow, turbulent flow, or intraluminal clot with MRA. Because almost all aneurysms larger than 3 mm

Fig. 8-3. MRI and MRA examination demonstrating flow effects associated with a giant left cavernous carotid aneurysm. *A*, Axial short TE, long TR MR image demonstrating the aneurysm (long arrow) with internal and external phase encoding artifact (short arrows) due to mismatched flow. *B*, Sagittal T1-weighted image falsely gives the appearance of thrombus within the aneurysm (arrow) due to slow flow. *C*, Three-dimensional time-of-flight MRA poorly outlines the aneurysm (arrow) because of internal slow flow. *D*, AP view of left carotid angiogram confirms giant left cavernous carotid aneurysm (arrow). (Case courtesy of Daryl Harp, MD.)

can be visualized,¹⁴⁹ MRA can function as a screening examination.^{45, 240}

The most commonly employed sequence is TOF three-dimensional (3D) MRA, which typically provides submillimeter in-plane resolution. A variant of this is MOTSA (multiple overlapping thin-slab acquisition),^{33, 34, 232} which attempts to combine the advantages of 3D with two-dimensional (2D) MRA. MOTSA is especially helpful when the slow flow in an aneurysm located distally within the imaging slab is not imaged on a 3D TOF study because of flow saturation. The T1 shortening effect of subacute subarachnoid blood or intraluminal or perianeurysmal clot can obscure an aneurysm or mimic flowing blood on a TOF imaging sequence.¹²⁶

An alternative pulse sequence is phase-contrast (PC) MRA, which has excellent background, susceptibility artifact, and stagnant blood suppression and may help image in-plane flow and slow flow, two causes of flow saturation degradation of TOF MRA.^{73, 127} It can be combined with cardiac gating using electrocardiogram leads or peripheral photoplethysmography to create cine PC MRA, a technique that has been used to document a greater pulsatility change in aneurysm size with ruptured than with unruptured aneurysms.³⁰² PC MRA has poorer spatial resolution, depends on a prescribed velocity encoding gradient with the potential for aliasing, can be altered by complex flow, and requires longer imaging and processing times than TOF MRA.¹²⁷ Although PC MRA may identify fewer aneurysms

than TOF MRA,¹³⁷ the slow flow within fusiform aneurysms is often better imaged with PC MRA. A patent double lumen in a dissecting aneurysm would also be best imaged with PC MRA.

MRA combined with MRI can often demonstrate internal flow patterns within large and giant cerebral aneurysms; faster flow is located more peripherally, and stagnant flow more centrally.^{97, 102, 298} Vascular loops may be confused with cerebral aneurysms on MRA. Gadolinium-based intravenous contrast agents are not typically employed in the identification of cerebral aneurysms but can be helpful to highlight aneurysms that are small, are in atypical locations, or have slow or stagnant flow or to document the residual patent lumen in an incompletely thrombosed aneurysm.^{252a} The use of contrast enhancement with MRI or MRA increases flow-dependent artifact and can obscure cerebral aneurysms because of enhancement of dural sinuses, intracranial veins, and extracranial structures,⁵⁹ unless a PC MRA technique is utilized.¹²⁷ In large or giant, partially or completely thrombosed aneurysms, the aneurysmal wall may show enhancement.

Special MRI techniques may help in the positive identification of cerebral aneurysms; they include magnetization transfer pulses,^{75, 146} progressive increases in radiofrequency pulse flip angles, and multiple postprocessing algorithms.^{21, 123, 169} It is important that both the 3D reconstructed MRA images and the source, 2D planar images are scrutinized, so that small aneurysms and aneurysms with slow flow are not missed. Standard maximum intensity projection (MIP) images have some artifact-derived limitations.³ Targeted MIPs select a region of interest and help exclude confounding extraneous vessels and other structures.¹²⁷ Review of the source images also best demonstrates the neck of the aneurysm and its relationship to the parent vessel. Vessel loops and magnetic susceptibility artifact from air-filled sinuses or bone at the skull base may obscure aneurysms.

CT angiography (CTA) is a relatively new development that can well demonstrate the morphology and location of cerebral aneurysms. Thin-section spiral CT slices are acquired during rapid intravenous infusion of a contrast agent. The axial images and the reconstructed 3D images, created with MIP and other processing methods, reproduce the proximal cerebral vasculature for analysis.^{207, 216, 217} Both the source images and the reconstructed images should be reviewed.³⁴⁵ The exclusion of adjacent skull base bone and the contrast enhancement of nonarterial structures can be problematic.²⁷⁴

3D CTA has a reported sensitivity of 67% to 90% for identifying cerebral aneurysms.^{274, 345} Aneurysms less than 5 mm in diameter may be missed.³⁴⁵ CTA has some benefits over MRA for evaluation of calcified atherosclerotic disease of adjacent vessels and, in some instances, for visualization of the aneurysm neck or dome and their relationship to osseous skull base structures such as the anterior clinoid process. 3D rotational views of both CT angiograms and MR angiograms help elucidate the precise anatomic relationships of cerebral aneurysms with adjacent vessels. Software reconstruction enhancements can provide endoscopic views of the dome and neck of an aneurysm.^{188a}

Catheter cerebral angiography remains the standard for evaluation of cerebral aneurysms. Catheter-based angiography has better spatial resolution than MRA or CTA, but it

evaluates only the intraluminal portion of the aneurysm that contains flowing blood. The inability of catheter cerebral angiography to demonstrate aneurysmal clot can lead to underestimation of the size of the aneurysm. This deficiency of catheter cerebral angiography is significant in comparison with MRI, which can demonstrate not only clot but also its age as well as the relationship of the aneurysm with adjacent brain structures. Cerebral angiography has the benefit, however, of better demonstrating cerebral vasospasm, the aspects of the aneurysm's morphology, such as dome irregularity or lobulation, which are possible predictors of hemorrhage, and a focal tit or dimple indicating the site of recent aneurysmal hemorrhage.³⁴⁰ Aneurysms evaluated soon after rupture often are smaller than when intact, because of clot compression and spasm of either the aneurysm or adjacent artery, but they subsequently enlarge if surgery is delayed.^{141, 209, 273, 326}

Cerebral Aneurysm Evaluation after Surgery

Controversy has arisen regarding the use of MRI to evaluate patients who have undergone cerebral aneurysm clipping. Most cerebral aneurysm clips are currently MRI compatible^{281a} but create local ferromagnetic artifact on MRI that obscures precise evaluation of the neck of the clipped aneurysm (Fig. 8-4).¹⁰³ Issues have been raised regarding clip-to-clip variability, distortion of the aneurysm clip during surgical application, manufacturer liability, warnings from the U.S. Food and Drug Administration regarding rotational and translational aneurysm clip motion in a magnetic field, and the necessity of institutional assurance that all aneurysm clips are MR compatible.^{139b} Because of these issues, many facilities have denied MRI to patients with cerebral aneurysm clips, even though an MRI permits better evaluation of brain parenchyma than CT. In fact, fatal cerebral hemorrhage attributed to the MR's magnetic field has been reported in a patient in whom a stainless steel, MRI-incompatible aneurysm clip had been placed on a middle cerebral artery aneurysm.¹⁴⁶

Guglielmi detachable platinum coils, which are used to treat cerebral aneurysms endovascularly, are MRI compatible.^{67a, 281a} However, localized artifact caused by the platinum coils on either MRI or CT often do not permit precise evaluation of the aneurysm.^{66a, 96a, 313} Less metallic artifact is present in both the endovascularly treated and surgically clipped aneurysm patient than CT.¹³⁶ Catheter angiography remains the only method to determine whether the aneurysm has been completely clipped or coiled.

Cerebral Vascular Malformations

Cerebral vascular malformations can be divided into four primary types^{38, 194, 258}:

- Arteriovenous malformation (AVM)
- Cavernous angioma
- Capillary telangiectasia
- Venous angioma

These types of vascular malformations can also be mixed—incorporating elements of two or more types.^{23, 74, 98, 219, 246, 247, 305} The four classic types of cerebral vascular

Fig. 8-4. Ferromagnetic artifact produced by cerebral aneurysm clip on MRI. Short TE, long TR (A) and coronal post-contrast T1-weighted (B) images demonstrating an ophthalmic aneurysm clip (arrows).

malformations are based on their congenital origin and do not include acquired arteriovenous cerebral fistulas, which are dural in location, or acquired or congenital direct arteriovenous fistulas. The term *occult cerebral vascular malformations* has been used to describe cavernous angiomas, capillary telangiectasias, and thrombosed AVMs because they could not be visualized with catheter cerebral angiography. Because all of these lesions, except some capillary telangiectasias, can be demonstrated on MRI, they are no longer truly "occult," and the term therefore has little current relevance.

The overall incidence of vascular malformations of all types in the general population is estimated to be 2%.

Arteriovenous Malformations

Incidence and Pathology

Approximately 0.1% of the general population harbor a cerebral AVM, the most common symptomatic cerebral vascular malformation.²³⁵ AVMs are most commonly identified in women in the second to fourth decades.³³² Roughly 30% to 55% of patients present with intracranial hemorrhage,^{2, 43, 58, 223, 237} a heralding event that is also most common in children with cerebral AVMs. Seventy percent of patients with intracranial hemorrhage due to AVMs present prior to age 40.^{20a, 43, 94} Intracranial hemorrhage is most commonly intraparenchymal but may be intraventricular or subarachnoid. Nontraumatic subarachnoid and intraventricular hemorrhages are more commonly due to rupture of cerebral aneurysms. Spontaneous thrombosis of a draining vein and rupture of a nidal aneurysm are believed to be the most common causes of AVM hemorrhage. Exclusive central venous drainage and a periventricular or intraven-

tricular location have been reported as other characteristics indicating a propensity for AVM hemorrhage. Peripheral venous drainage or mixed peripheral and central venous drainage, along with angiomatous change, dilated arterial collaterals that pass through brain to supply the AVM, have been correlated with a decreased incidence of AVM hemorrhage.^{185, 186} AVMs 3 cm or less in diameter have been reported to bleed more frequently and to produce larger hematomas than larger AVMs.^{195, 238} The rate of hemorrhage of a cerebral AVM is estimated to be 2% to 3.5% per year and to increase with advancing age; this figure is higher than the yearly rupture rate for cerebral aneurysms.^{20a, 43, 58, 99, 116, 223, 294} Mortality of 10% to 30% is associated with each instance of hemorrhage, for an overall annual mortality rate of less than 1%. The risk of permanent neurologic deficit is 20% to 30% with each AVM hemorrhage,^{20a, 43, 94} resulting in an annual incidence of approximately 1%. The risk of rebleeding after a first hemorrhage is approximately 6% in the first year⁹⁹ and subsequently decreases to an annual rate of 3%.^{43, 235, 303, 309}

The second most common clinical presentation of cerebral AVMs is seizures, which are reported in 22% to 60% of cases.^{99, 196, 235, 237, 322} Seizures manifest more commonly in patients who are younger than 30 years and with AVMs that are large or diffuse. Large AVMs are also more commonly identified with progressive neurologic deficit. The overall risk of a seizure disorder in a patient with an AVM is 18%, and the risk of a neurologic deficit is 25% to 30%.^{4, 43, 58} There is an approximately 1 in 4 risk that a patient will become intellectually disabled because of a brain AVM, without or with previous hemorrhage.

Brain AVMs cause nonhemorrhagic symptoms because of (1) blood flow steal from adjacent normal territories and

(2) regional venous hypertension due to the engorged, high-flow, draining veins of the AVM. Clinical sequelae are seizures, neurologic deficit, and headache. Acute neurologic deficits, however, are most commonly associated with intracranial hemorrhage due to an AVM. Occasionally, brain AVMs can result in mass effect or hydrocephalus due either to vascular compression of CSF pathways or communicating hydrocephalus secondary to previous hemorrhage. Headache is identified in more than 50% of patients with brain AVMs.³⁴¹ Thirty percent of patients report a bruit, which is due to transmission of blood pulsations from the AVM.⁴³ Calvarial auscultation of a cranial bruit is unusual, however. Occasionally, an AVM may cause either hemifacial spasm or cranial nerve neuralgia or palsy if the AVM in whole or in part is located in the basilar cisterns³⁴¹ or if subarachnoid hemorrhage has occurred previously.

More than 80% of cerebral AVMs are located supratentorially, and the remainder within the posterior fossa. AVMs may be multiple in up to 2% of patients,²⁶³ often as part of Rendu-Osler-Weber disease,² an autosomal dominant inherited condition in which mucosal, skin, gastrointestinal, and cerebral hereditary hemorrhagic telangiectasias, brain cavernous angiomas, and pulmonary AVMs are also found (Fig. 8-5), and in the Wyburn-Mason syndrome (also termed mesencephalo-oculofacial angiomatosis), which is signified by the presence of cutaneous nevi and retinal angiomas together with brain AVMs.^{201, 336} AVMs may also be located extracranially or intracranial AVMs may be associated with additional extracranial AVMs.

Pathologically, the cerebral AVM represents a direct communication between arteries and veins without intervening capillaries,^{10a, 140, 221} the communicating vascular channels being larger than capillaries yet arbitrarily smaller

than fistulas. Fistulas often reside within the AVM nidus, however. The nidus represents the central compact tangle of low-resistance vessels constituting the junction of the feeding arteries and draining veins. The nidus does not contain normal brain parenchyma, although the enlarged feeding arteries and draining veins can traverse normal tissue.⁴⁹ Large, diffuse AVMs may contain normal neurons and white matter, however.^{54a} Brain AVMs may be located in the subarachnoid space, intraparenchymally, or intraventricularly or may transgress several spaces, including the cranial vault. The AVM nidus volume together with characteristics such as the presence of fistulas, the chronicity of the lesion (the age of the patient), and the rate of flow through the AVM determine the size and tortuosity of feeding arteries and draining veins.

AVMs may be supplied by any of the cerebral vessels, including meningeal contributors in 15% to 50% of cases.¹⁹⁸ Approximately 10% of AVMs have an arterial feeder, nidus, or remote arterial aneurysm,^{186, 232, 339} the flow-related aneurysms most often located on feeding vessels.^{60, 148, 199, 232} Some of these flow-related aneurysms are pseudoaneurysms.²³⁴ The aneurysms contribute to the incidence of hemorrhage from AVMs.³³⁹ Varices can develop in draining veins and can become quite large. Areas of stenosis, thrombosis, or occlusion can occur in supplying arteries or exiting veins. The findings of vascular stenoses and aneurysm formation are attributed to local hemodynamic stresses.²³⁴

Histologic examination of cerebral AVMs demonstrate thickened walls of both variably enlarged feeding arteries and draining veins, the walls demonstrating smooth muscle hyperplasia, fibroblast infiltration, and increased connective tissue. Arteries are differentiated from veins on the basis

of the presence of elastic lamina and muscular layers within arteries. Adjacent brain parenchyma may exhibit atrophy, gliosis, and demyelination^{49, 220, 222} due to ischemic steal by the AVM,⁵² compressive mass effect, venous hypertension, and prior hemorrhage. If previous hemorrhage has occurred, ferritin and hemosiderin staining of brain will be demonstrated. Calcification may be identified within component vessel walls as well as in adjacent brain parenchyma because of chronic venous hypertension or hemorrhage. Overlying leptomeninges may be thickened by venous engorgement or as a result of previous hemorrhage, which is also denoted by hemosiderin or ferritin staining.^{50a}

The most commonly used AVM grading system was proposed by Spetzler and Martin.²⁹¹ This system assigns a numerical grade to the AVM on the basis of the size of the nidus, the location of the nidus in relationship to eloquent functional brain, and the venous drainage (superficial or deep) (Table 8–2). The intent of such a grading system is to predict therapeutic risk and outcome, and its application is fairly simple; the details of many AVMs are not completely explained by this classification system, however.

The therapy of brain AVMs is based on one of the following four options: conservative observation, surgical resection, radiosurgery, and endovascular embolization. The various treatment options may be combined. Complete surgical resection has been reported in approximately 80% of brain AVMs, with morbidity and mortality rates reaching approximately 10% regardless of AVM grade.¹¹⁶ Radiosurgery is typically employed for brain AVMs that are 3 cm or less in diameter, but it can be used for an AVMs whose nidus is larger. Radiosurgery has obliterated AVMs at 3-year follow-up in more than 80% of reported series. The procedure has a complication rate of less than 3%, adverse events being most often due to radiation necrosis.^{79, 174, 175, 294, 295} Embolization is often performed to reduce the flow and size of brain AVMs prior to surgical resection or radiosurgery, but in a few instances, complete cure can be achieved with embolization alone.³⁰

CT and MRI

CT imaging of brain AVMs demonstrates a focal collection of isointense to slightly hyperintense vessels on unenhanced scans but may be completely unremarkable without the administration of a contrast agent. Acute hemorrhage is well documented when present.²³ Occasionally, mass

effect, surrounding edema, calcification (25% to 30% of cases), or adjacent brain atrophy may be identified.¹⁵³ Intravenous contrast enhancement is essential for identifying the typical “bag of worms” appearance of a brain AVM as well as its enlarged supplying arteries and draining veins.

MRI examination is, for the most part, superior to CT for identifying and evaluating cerebral AVMs. MRI not only outlines the nidus and permits evaluation of its size but also identifies supplying arteries and draining veins. A cluster of vessels of variable signal intensities, depending upon the imaging sequences used, characterize the AVM nidus. Flow-dependent phenomena such as dephasing, rephasing, slow flow, entry slice enhancement, and phase encoding mismatching may all be demonstrated (Fig. 8–6).³⁹ Most often, the nidus vessels demonstrate signal void on spin-echo pulse sequences and bright signal intensity on gradient-echo sequences, findings that are also typical within enlarged feeding arteries and draining veins. Adjacent brain parenchyma can be well evaluated for edema or gliosis, which has bright signal intensity on T2-weighted spin-echo studies (Fig. 8–7).^{50a, 287} MRI is crucial for localizing the AVM in relationship to eloquent cortex or deeper gray matter structures and significant white matter fiber tracts as well as demonstrating any mass effect. MRI well demonstrates the expected evolutionary appearance of acute, subacute, and chronic hemorrhage. Chronic hemorrhage with resultant ferritin- or hemosiderin-stained brain, including superficial or ependymal hemosiderosis,^{50a, 95, 287} is displayed as areas of parenchymal decreased signal intensity on T2-weighted spin-echo and T2*-weighted gradient-echo sequences.⁵² Gadolinium-based contrast agents are of limited if any utility in the MRI evaluation of cerebral AVMs because of inconsistent enhancement and the production of excessive flow artifact. Functional MRI utilizes cortical blood flow changes based on deoxyhemoglobin levels to create activation maps, which may be used to evaluate brain function adjacent to an AVM before therapeutic interventions are undertaken.^{122, 178} In some instances, the tested neurologic function is expressed in an unexpected cerebral region secondary to neural plasticity, a consequence of the congenital nature of the AVM and the development of alternative neural circuits.¹⁷⁸

MRA and CTA can help in the evaluation of cerebral AVMs, but these studies may be nonrevealing for AVMs that are small or have slow flow. CTA and MRA of the circle of Willis as well as the territory containing the nidus must be performed so that all critical features of the AVM are imaged. Evaluation of the source planar images acquired during MRA may reveal a small AVM as bright vessels differentiated from intravascular or extravascular clot, which may obscure an AVM on conventional MRI and the reconstructed 3D MRA. Both TOF and PC methods can be used in MRA examinations.¹⁸⁸ MOTSA and PC MRA are better suited to diagnose AVMs with slow flow.^{33, 188} MRA is notorious for incompletely visualizing AVMs because of variable flow effects and related artifact. Aneurysms are frequently unidentifiable. Both MRA and CTA have difficulty discriminating the AVM’s supplying arteries from draining veins. The precise angioarchitecture of cerebral AVMs is best demonstrated with traditional catheter angiography, which can identify flow-related and nidus aneurysms, the rate of AVM flow, characteristic early

Fig. 8-6. A, Short T1-weighted axial MR image illustrates a cerebral AVM draining from cortical to ventricle. The AVM nidus is of decreased signal intensity due to rapid flow, which produces phase encoding artifact (arrow). B, Axial T2-weighted MR image demonstrates some of the AVM's draining veins (short arrows) and less uniform decreased signal intensity in smaller nidus vessels, some of which have increased signal intensity (long arrow). C, Coronal T1-weighted MR image illustrates the triangular shape of the AVM. D, Coronal T1-weighted contrast-enhanced image illustrates variable contrast enhancement of the AVM's nidus due to differential flow rates, faster flow producing less enhancement. Note the phase encoding artifact (arrow).

filling veins, all of the contributing arteries and draining veins, and arterial and, particularly, venous stenoses.

The differential diagnosis of cerebral AVMs is limited. Incompletely or totally thrombosed AVMs can appear similar to other masses, including vascular neoplasms such as hemangioblastoma. When a thrombosed AVM has an accompanying intraparenchymal hematoma, differentiating it from a hemorrhagic metastasis, a high-grade glioma, or a nonmalignant cause of hemorrhage, such as hypertension or amyloid angiopathy, can be difficult.

Occasionally, moyamoya can mimic basilar cistern or basal ganglia AVMs. An unusual occurrence in North America, moyamoya is more commonly identified in Japan. It may manifest as intraparenchymal (60%), intraventricular (40%), or, rarely, subarachnoid hemorrhage,^{300, 344} tran-

sient or permanent ischemic stroke, or seizures and is seen in both children and adults. The most typical age at presentation in adults is in the fourth decade. Moyamoya is characterized by progressive obliteration of large proximal anterior circulation vessels with the development of small "puff of smoke" arterial collaterals. Causes of findings similar to those of moyamoya include neurofibromatosis, sickle cell disease, prior radiation therapy, and Down syndrome. The MRI appearance of moyamoya is notable for the numerous small vessels seen within the inferior brain substance, which represent the collaterals for severely narrowed or occluded distal internal carotid or proximal anterior or middle cerebral arteries.^{86, 112} Hemorrhage or infarction may also be demonstrated.

MRI examination is also well suited to evaluate cerebral

Fig. 8-7. Brain AVM with bordering reactive astrocytosis (gliosis). *A*, T2-weighted axial MR study demonstrating a high flow right frontoparietal AVM. Draining vein (*arrow*). *B*, More inferior T2-weighted axial section reveals enlarged right MCA and ACA branches (*arrows*) supplying the AVM. *C*, Coronal T2-weighted image illustrating the AVM's extent from cortex to ventricle. *D*, FLAIR image highlighting reactive astrocytosis (gliosis) bordering the AVM, seen as bright signal intensity (*arrow*).

AVMs after therapy, particularly radiosurgery or embolization,^{145, 287} to demonstrate decreased size and reduced flow.^{174, 182, 183} The use of a contrast agent is helpful for identifying any residual AVM nidus; however, contrast enhancement may also be secondary to postoperative gliosis, radiation necrosis, or infarction. Hemorrhage may sometimes occur as a component of radiation necrosis, which may develop as soon as 3 months after radiation therapy. Perinidal edema after radiosurgery, seen as increased signal intensity on T2-weighted spin-echo MR images, is expected and does not necessarily indicate impending radiation necrosis.

Cavernous Angioma

Cavernous angiomas account for approximately 10% to 15% of all cerebral vascular malformations,²²⁹ and are found in approximately 0.4% of the general population.²³⁴ They are the second most common type of symptomatic vascular malformation. Cavernous angiomas typically present as focal parenchymal intracranial hemorrhages between the third and fifth decades of life. Those found in the brain occur equally in males and females. The most common location is in the cerebral hemispheres, with only 10% identified in deep gray matter or white matter tracts. Approximately 25% are found infratentorially, in equal numbers within the brain stem and cerebellum. The pons is the most common location in the brain stem. Unusual cases may arise from the leptomeninges,^{276, 285} dura, ependyma, choroid plexus, or cranial nerves, or extradurally. In 30% to 50% of cases, cavernous angiomas are multiple. Spinal cord cavernous angiomas may be isolated or may be associated with cerebral cavernous angiomas.³⁷ A genetic predisposition manifests when cavernous angiomas are found in 10% to 15% of family members in addition to the index case.^{31, 57, 245} When a familial tendency exists, the propensity for multiple cavernous angiomas rises to 80%.³⁴⁶ Multiple cavernous angiomas can be seen in Rendu-Osler-Weber disease.

The clinical presentation of cavernous angiomas typically consists of seizure activity or of acute or progressive neurologic deficit due to cerebral hemorrhage,²⁴⁷ but in one study, only 61% of patients were symptomatic.^{49, 55, 250, 346} Seizures, the most common symptom, occur in approximately 50% of patients. Seizures are believed to be secondary to mass effect from the cavernous angioma and adjacent brain parenchymal hemosiderin or ferritin and gliosis. Symptomatic hemorrhage manifesting as headache, seizures, or acute neurologic deficit most often occurs in the second and third decades of life and has an incidence of approximately 0.5% to 1% per year.^{28, 61, 250} Subclinical hemorrhage is not uncommon, and clinically significant hemorrhage occurs in only 10% to 13% of cases.⁴⁹ Hemorrhage from a cavernous angioma uncommonly extends into the ventricular system or the subarachnoid space. It is unclear whether cavernous angiomas, once having bled, have a propensity for subsequent hemorrhage. Cavernous angiomas may initially be tiny and grossly unrecognizable, then suddenly enlarge because of new hemorrhage and thrombosis. They often change over time in size, shape, and character because of intermittent and recurrent hemorrhage and thrombosis, recannulization, vascular ingrowth,

and granulation tissue.^{37, 284} When an angioma is large enough, mass effect can produce cranial nerve palsies and focal neurologic deficits. Cranial radiation therapy may cause thrombosis and hemorrhage to develop in preexistent, unrealized cavernous angiomas, making them appear as new findings on serial MRI studies.

On pathologic examination, cavernous angiomas are well circumscribed and have a mulberry configuration. The lesions are not encapsulated but contain a compact or sometimes racemose network of multiple endothelium-lined, sinusoidal, nonuniform vascular channels containing thrombosed blood of varying ages.^{49, 220} Compartment walls are irregularly thickened with collagen, hyalin, and scattered calcium deposition and contain no muscularis or elastic lamina layers. No interposed brain tissue is identified within the cavernous angioma. Adjacent brain may be calcified, laden with hemosiderin or ferritin, atrophic, and gliotic. Cavernous angiomas are typically parenchymal lesions sometimes marginating a pial or ependymal surface. Capillary telangiectasias may coexist with or may be mixed with the cavernous angioma.^{23, 210} Venous angiomas may also coexist.^{98, 247, 305}

CT and MRI

CT scans of cavernous angiomas typically demonstrate an isodense to hyperdense focal area within the brain parenchyma that may or may not contain calcification (Fig. 8–8). They may or may not enhance after intravenous administration of an iodinated contrast agent.²⁶⁹ Mass effect

Fig. 8–8. CT examination without contrast of a pontine cavernous angioma demonstrating focal calcification (curved arrow) and peripheral (short arrow) and central (long arrow) hemorrhagic degradation products.

Fig. 8-9. MRI examination of a cavernous angioma demonstrating typical variegated appearance containing hemorrhage of varying ages. **A**, T2-weighted image of a right subinsular/lenticular nucleus/thalamic/internal capsule cavernous angioma. Note the peripheral hemosiderin/ferritin (*long arrow*) and edema located at the site of recent hemorrhage (*short arrow*). **B**, T1-weighted image without contrast. Note the subacute hemorrhage (*arrow*). **C**, T1-weighted image with contrast. Note the lack of appreciable contrast enhancement. (Case courtesy of David Watts, MD.)

and edema associated with the cavernous angioma may be present, depending on its size.¹⁵²

MRI is superior to CT for the identification of cavernous angiomas.²⁴⁵ It typically demonstrates a mass characterized as popcorn in appearance owing to the varying ages of internal hemorrhages.⁹⁶ The margin of the cavernous angioma is of decreased signal intensity on T2*-weighted gradient-echo and T2-weighted spin-echo images if chronic hemorrhage is present.⁹⁶ This finding is due to the magnetic susceptibility-caused phase incoherence created by the he-

mosiderin and ferritin residua from previous hemorrhage (Fig. 8-9).³⁷ The signal intensity of the rim of the cavernous angioma is also decreased because of fibrin and collagen deposition. T2*-weighted gradient-echo scans, which are best for the identification of hemosiderin and ferritin, should always be performed in the evaluation for intracranial hemorrhage. In some cases, the T2* gradient-echo study reveals multiple cavernous angiomas when the T2-weighted spin-echo study illustrates only a solitary lesion. Hemosiderin and ferritin may cause a dark flaring appear-

ance extending into the adjacent brain parenchyma because macrophages and astrocytes remove blood breakdown products, including hemosiderin and ferritin, along white matter fibers.⁴⁹ Owing to MRI's exquisite sensitivity for blood degradation products, cavernous angiomas may be incidentally discovered as asymptomatic lesions.²⁴⁵ Gadolinium-based contrast agents typically produce some enhancement of the cavernous angioma.

Unusual extra-axial cavernous angiomas may have a typical or atypical MRI appearance. Extra-axial cavernous angiomas may resemble meningiomas with homogeneous, intense contrast enhancement but bright signal intensity on T2-weighted spin-echo images.^{142, 150, 171}

Catheter cerebral angiography is indicated only to exclude a true arteriovenous malformation as the cause of intracranial hemorrhage when the diagnosis of cavernous angioma using MRI is uncertain. Catheter angiography displays cavernous angiomas as avascular masses, occasionally demonstrating very late capillary staining without arteriovenous shunting.²⁶⁹ When present, an associated venous angioma may be demonstrated.

Therapy for cavernous angiomas consists of medical treatment for seizure control, surgical excision when the lesion is accessible and clinically indicated, and radiosurgery.

The differential diagnosis of cavernous angiomas includes previous hypertensive hemorrhage, treated toxoplasmosis, previous radiation therapy, amyloid angiopathy, and disseminated intravascular coagulopathy. The demonstration of a lesion containing hemorrhages of multiple ages, a complete peripheral hemosiderin/ferritin ring with flaring into neighboring brain, and the lack of surrounding edema help differentiate cavernous angioma from hemorrhagic metastasis; in some instances, however, particularly with melanoma, only follow-up MRI examinations documenting typical hemorrhage evolution confirm the diagnosis of cavernous angioma.

Capillary Telangiectasia

Capillary telangiectasias are small, usually clinically silent lesions that most commonly occur in the pons or cerebellum but can occur in other locations in the brain parenchyma. They are the second most common cerebral vascular malformation, after venous angiomas, and are usually multiple.²²² The histology of capillary telangiectasias is characterized by dilated, thin-walled capillaries. Unlike cavernous angiomas, normal brain parenchyma is identified within the capillary telangiectasia.^{49, 220} Adjacent brain is most often normal but may contain gliosis or hemosiderin/ferritin from previous hemorrhage.⁴⁹ Capillary telangiectasias are believed to bleed rarely, however.

Other types of cerebral vascular malformations can be found together with capillary telangiectasias, especially cavernous angiomas.²⁴⁷ Cerebral capillary telangiectasias can be found in Rendu-Osler-Weber disease, also known as hereditary hemorrhagic telangiectasias, along with telangiectasias in other visceral, mucosal, and cutaneous sites plus pulmonary and cerebral true AVMs. Approximately 28% of patients with Rendu-Osler-Weber disease have cerebral AVMs, with cerebral capillary telangiectasias being less common.^{2, 167} Cerebellar capillary telangiectasias may also be a component of the ataxia-telangiectasia syndrome.

CT and MRI

Capillary telangiectasias are most often not identified on unenhanced MRI studies using all available pulse sequences. Rare capillary telangiectasias that have hemorrhaged demonstrate expected MR findings of blood. Most often the hemorrhage is minor and remote, best demonstrated on T2*-weighted gradient-echo studies. Enhancement with gadolinium-based contrast agents demonstrates a lacy network of vessels constituting the capillary telangiectasia (Fig. 8–10). A coexisting cavernous angioma may

Fig. 8–10. Contrast-enhanced T1-weighted MRI examination (A) demonstrating a pontine capillary telangiectasia (arrow) that is not well visualized on the T2-weighted study (B).

obscure identification of the capillary telangiectasia.²³ CT usually demonstrates no abnormality.

Venous Angiomas

Venous angiomas are the most common cerebral vascular malformation, accounting for almost two thirds of the total and having an incidence in the general population of approximately 2%.^{156, 222, 266, 312} This vascular malformation represents a developmental variant of normal venous drainage,¹⁵⁶ composed entirely of venous elements, and some writers prefer to call them "developmental venous anomalies," dropping the term "angioma."¹⁵⁶ The association of venous angiomas with neuronal migration anomalies and the absence of normal venous drainage from regional brain containing the venous angioma emphasizes their embryologic origin (Fig. 8–11).^{156, 312} Typically solitary and located

in any part of the brain parenchyma, although most often in the frontal lobe, then the cerebellum,^{229, 318} venous angiomas range in size from small to large enough to drain an entire hemisphere.³¹² Multiple venous angiomas are not rare, particularly when they occur bilaterally in the cerebellum,³¹² and their multiplicity has been described in the blue rubber bleb nevus syndrome.

Venous angiomas are characterized by a medusa head of enlarged medullary veins draining to a collector vein, which continues to either the superficial or subependymal cerebral venous drainage system or a combination of these.^{98, 312, 318, 329} Venous angiomas are occasionally found intraventricularly. An unusual case of a venous angioma draining to the foramen of Monro and resulting in obstructive hydrocephalus has been reported.^{312, 318} The brain parenchyma through which the venous angioma passes is typically normal and shows no evidence of previous bleeding.

Fig. 8–11. Venous angioma associated with a neuronal migration anomaly. *A*, T2-weighted MR image demonstrates a right parietal schizencephalic cleft (*short arrow*) containing a venous angioma (*long arrow*). (Case courtesy of David Watts, MD.)

Some writers believe that venous angiomas may rarely cause venous infarction with or without hemorrhage, or hemorrhage alone, more often subarachnoid than parenchymal^{155, 160, 314, 318, 337, 339} the hemorrhage is possibly due to acquired venous outflow restriction by stenosis or thrombosis^{68, 156} secondary to hemodynamic stresses. A venous varix or ectatic component is rarely seen and is explained

by similar obstructive mechanisms or hemodynamic forces.¹⁵⁶ The higher incidence of associated contiguous cavernous angiomas in as many as one third of cases,^{98, 229} however, is often used to explain any clinically significant hemorrhage being derived from the cavernous angiomas (Fig. 8-12).^{23, 170, 192, 247, 312} Rarely, seizures, focal neurologic deficit, cerebellar signs, tinnitus, and headache have been

ascribed to venous angiomas,^{32, 156, 229, 314, 318, 337, 339} depending on their location, but these clinical presentations are controversial.

CT scanning of a venous angioma demonstrates a contrast-enhancing vascular structure with a thistle-shaped collection of veins coursing to a single dominant draining vein (Fig. 8-13).^{312, 318} Calcification of these lesions is unusual, and without calcification, they are typically not identified on unenhanced CT scans. A large venous angioma, however, may be demonstrated by CT as a slightly dense solitary vessel or collection of vessels.³¹⁸

MRI best demonstrates venous angiomas and has revealed their true incidence in the general population. A venous angioma appears as a cluster of small vessels with signal void if flow within them is rapid or dephased; or the vessels may produce increased signal intensity due to slow flow, entry slice phenomena, even-echo rephasing, or when gradient-moment nulling techniques are utilized. Spatial misregistration artifact occurs in venous angiomas when gradient-moment nulling techniques are used on T2-weighted spin-echo images.¹⁵⁴ T2*-weighted gradient-echo techniques or TOF or PC MRA can demonstrate venous angiomas as a bright grouping of veins if the flow is fast enough or if MRA techniques crafted to take advantage of slow flow, such as thin-slice, 2D TOF, oriented perpendicular to venous inflow are employed (Fig. 8-14).²²⁹

MRA is typically not necessary to image venous angiomas, however. The rate of blood flow within the venous angioma usually depends on its overall size and determines its signal intensity on MRI³³⁷ together with its orientation to the plane of acquisition. Contrast-enhanced T1-weighted spin-echo or gradient-echo MRI sequences best demonstrate venous angiomas and their relationship to adjacent

brain parenchyma.^{229, 337, 339} Contrast-enhanced CT or MRI may reveal a focal parenchymal stain around the venous angioma's caput medusa. Frequently, venous angiomas are imaged on MRI as incidental findings because most are clinically silent. They also can be overlooked on MRI scans if small and similar to normal venous drainage.

Venous angiomas should be differentiated from aberrant venous drainage on the basis of the classic findings of a cluster of enlarged medullary veins continuing into a larger collector vein in venous angiomas, anomalous veins lacking more than one or two visualized upstream small veins. The MRI appearance of venous angiomas is so characteristic that catheter cerebral angiography should not be performed in their evaluation. It should be noted that small venous angiomas can be overlooked on catheter cerebral angiography, being thought another example of variant venous drainage, although characteristically they appear later and persist longer than normal veins.²²⁹

Sinus Pericranii (Fig. 8-15) is a soft, compressible venous malformation that by definition lies adjacent to the skull and communicates with the intracranial dural sinuses, most often by enlarged emissary veins.^{35, 260} Its etiology is most likely congenital, although it has been reported to occur spontaneously or after trauma.^{35, 260} Sinus pericranii may be associated with other vascular malformations, such as cavernous angiomas and venous angiomas, or may be seen as a component of the blue rubber bleb nevus syndrome.^{35, 260}

MR venography examination demonstrating typical characteristics of a venous angioma. *A*, Slightly oblique lateral and *B*, is a posterior coronal view of a left frontal venous angioma (arrows) demonstrated on MR venography. Lateral view of venous phase during carotid angiography confirms the venous angioma (arrow).

Sinus pericranii most commonly occurs in the frontal scalp near the midline.^{35, 260} An asymptomatic cosmetic scalp lump is found typically in a patient younger than 30 years. The lesion is twice as common in men as in women and is remarkable for its enlargement with Valsalva maneuvers.²⁶⁰

On imaging, sinus pericranii has been described as a vascular soft tissue scalp mass that is slightly hyperdense on unenhanced CT, demonstrates flow on MRI, and enhances strongly with use of a contrast agent on both CT and MRI.^{35, 260} CT best identifies associated osteolytic changes from the vascular mass and its associated diploic veins.^{35, 260}

Arteriovenous Fistulas Terminology

Arteriovenous fistulas (AVFs) are usually acquired⁵³ but may be congenital in some instances. Congenital fistulas most often represent an anomaly of cerebral vascular development and are part of a spectrum of cerebral vascular disorders. Single or multiple arterial venous connections or a true AVM nidus with one or more associated arterial venous fistulae illustrates the variety of pathologic presentations (Fig. 8-15). AVFs may be located intracranially or extracranially within the scalp or facial structures. The arterial venous shunting with increased venous pressure

Fig. 8-15. Congenital single arteriovenous fistula between a right middle cerebral artery branch and an adjacent cortical vein documented on MRI. *A* demonstrates an enlarged right middle cerebral artery (arrow) while *B* illustrates the enlarged angular artery (short arrows) and proximal draining vein (long arrow) on these T2-weighted images. *C* is the AP/Townes view of the right carotid injection confirming the fistula.

and flow within any of the AVFs can result in variably sized varices that, when large enough, can produce mass effect such as brain parenchymal or cranial nerve compression or obstructive hydrocephalus.^{65, 120, 121, 157, 179, 319, 320}

Most dural arterial venous fistulae are spontaneous and are believed to be acquired after thrombosis of the draining dural sinus with the subsequent development of multiple fistulous shunts to the involved sinus.^{121, 133} Chronic venous hypertension without dural sinus thrombosis has also been postulated.³⁰⁷ Other causes of dural AVFs are trauma, surgery, infection, systemic hypertension, and hypercoagulable

states, including pregnancy, contraception pills, and dehydration.^{27, 120, 121, 179} Another type of acquired AVF is best illustrated by the post-traumatic direct carotid cavernous fistula.

Dural AVFs are characterized pathologically by abnormal, direct communications between normal sinus wall arteries and veins.²¹¹ Hemodynamic stresses lead to pathologic disorganization and thickening (less commonly, thinning) of the walls of supplying arteries, draining cortical and medullary veins, and the dural sinus wall at the site of the fistula as well as thrombosis, stenosis, and occlusion of

the involved vascular elements, most commonly the dural sinus itself and least commonly the feeding arteries.^{121, 179, 211} Angiogenesis factors are probably involved in the propagation of dural AVFs.¹⁷⁹

Dural AVFs represent approximately 10% to 15% of intracranial vascular malformations^{45, 120, 190, 320} and are more common in women than men.³²⁰ Most often, the dural AVF involves a single sinus, sometimes with involvement of contiguous sinuses. Multiple disparate dural AVFs are rare⁴⁵ and are typically in close proximity,¹⁷⁹ even the bilateral dural carotid cavernous fistulas possibly related by the interconnecting circular sinus and clival veins.

Dural AVFs may spontaneously obliterate^{15, 179}; however, closure of such a lesion may be associated with intracranial hemorrhage.¹⁵⁷ Approximately 15% of patients present with intraparenchymal, subarachnoid, or subdural hemorrhage, listed in decreasing order of frequency.^{45, 120, 157} Significant in the production of intracranial hemorrhage is reversal of flow within the involved dural sinus into variably dilated cortical veins, which results in venous rupture or venous hypertension in the involved cerebral territory.^{120, 157, 238} The risk of hemorrhage from a dural AVF is 1.8% per year, with a 20% mortality for each hemorrhage.⁴⁵ Risk factors for producing hemorrhage include AVF location in the anterior cranial fossa (ethmoidal), superior petrosal sinus, or deep veins, leptomeningeal venous drainage, draining vein stenosis, and a venous varix.^{45, 110, 179, 190, 320}

Dural AVFs have been categorized on the basis of their venous drainage pattern (Table 8-3).^{55a} Over time, dural AVFs may change and so be assigned to a different type.¹⁷⁹ Symptomatology and risk of hemorrhage roughly correspond to more abnormal venous drainage.¹⁷⁹

Dural AVFs may also cause seizures or neurologic deficits owing to venous hypertension-caused hemorrhage or ischemia/infarction or, less commonly, to arterial steal.^{45, 121, 157, 304, 315, 320} Pulsatile tinnitus and headache, the most common complaints,^{45, 320} may be mild enough and of such chronicity that the patient does not seek medical attention until other symptoms develop, such as cranial nerve palsies due to arterial steal or abnormal venous drainage and congestion.¹⁵⁷ Dural AVFs most often become symptomatic in patients between 40 and 60 years of age.²²⁵

Communicating hydrocephalus may be the result of the dural AVF producing dural sinus hypertension, dural sinus thrombosis, or prior subarachnoid hemorrhage.¹⁵⁷ Increased intracranial pressure without communicating hydrocephalus

may be due to cerebral venous congestion, increased cerebral blood volume, elevated intrasinus pressure, and impaired cerebral venous drainage.^{121, 320}

Arterial supply to dural AVFs is from meningeal branches of the external carotid artery (e.g., the middle meningeal, ascending pharyngeal, and occipital arteries), the internal carotid artery (e.g., the tentorial artery of the meningohypophyseal trunk), and the vertebral artery (e.g., the posterior meningeal artery).^{45, 226} Pial arteries derived from the carotid or vertebrobasilar system can also supply dural arteriovenous fistulae.

In one third to two thirds of cases, dural AVFs involve the sigmoid and transverse sinuses.^{45, 49} The cavernous sinus is the second most common location, accounting for 12% to 20% of AVFs and being most common in middle-aged women.^{45, 65} The symptoms of cavernous sinus dural AVFs include palsies of cranial nerves III, IV, and VI, which produce diplopia, proptosis, conjunctival engorgement, retro-orbital or cranial nerve V pain, increased intraocular pressure and secondary glaucoma; all of these are due to the abnormal venous hypertension within the cavernous sinus and retrograde venous drainage into the involved orbit.^{120, 147, 306} More ominous consequences are papilledema, choroidal or retinal detachment, central retinal vein thrombosis, and diminished visual acuity.¹⁷⁹ Other sites of dural AVF are the tentorium and its incisura, the superior and inferior petrosal sinuses, the occipital and marginal sinuses, the superior and inferior sagittal sinuses, the straight sinus, the vein of Galen, and the anterior and middle cranial fossae.^{65, 190} Adjacent cortical veins may also incorporate AVFs within their walls.¹⁷⁹

Unenhanced CT scans of dural AVFs are normal unless intracranial hemorrhage, edema or infarction from venous hypertension, or thrombosis of a dural sinus or draining vein is identified. Contrast-enhanced scans may occasionally demonstrate enlarged cortical or medullary veins or stenotic or enlarged dural sinuses (Fig. 8-16). These findings are noted in up to half of patients with dural carotid cavernous fistulas, with expansion of the involved cavernous sinus and increased size of the draining superior ophthalmic vein.

MRI demonstration of cerebral AVFs depends on the type of fistula encountered. With congenital direct AVF, MRI demonstrates an enlarged supplying artery that communicates directly within an enlarged draining vein (see Fig. 8-15). In a post-traumatic direct carotid cavernous fistula, MRI shows enlargement of the cavernous sinus containing diminished signal intensity due to excessive blood flow within the sinus, and dilated superior and inferior ophthalmic veins as well as other smaller orbital veins with accompanying orbital proptosis and extraocular muscle enlargement. Dural carotid cavernous fistulas often show similar but less dramatic findings.¹⁴⁷ Either type of carotid cavernous fistula may produce bilateral cavernous sinus and orbital findings on MRI because of intersinus midline venous communications. The MRI findings with dural AVFs are more subtle if the more easily appreciated findings of intracranial hemorrhage, edema, or infarction are not present.

MRI and MRA are notorious for missing uncomplicated dural AVF unless the venous drainage into enlarged cortical or medullary veins is demonstrated.⁶⁵ In such instances,

TABLE 8-3. Classification of Dural AVFs

Type I	
Antegrade drainage into sinus	
Type II	
II a	Antegrade and retrograde drainage into sinus
II b	Antegrade drainage into sinus and retrograde drainage into cortical veins
II a & b	Antegrade drainage into sinus and retrograde drainage into sinus and cortical veins
Type III	
Retrograde drainage into cortical veins	
Type IV	
Retrograde drainage into cortical veins with venous ectasia	
Type V	
Drainage into spinal veins	

Fig. 8-16. Contrast-enhanced CT examination of a congenital superior sagittal sinus dural arterial venous fistula demonstrating (A) an enlarged superior sagittal sinus (arrow) and subcortical calcifications (small arrows) and (B) an enlarged torcula (long arrow), right transverse sinus and tentorial veins (open arrow), and deep perimesencephalic veins (small arrows). Note also the subcortical and lenticular nuclei calcifications (small curved arrows). C, Lateral left external carotid angiogram illustrates left middle meningeal branches (arrows) and left occipital branches (curved arrow) supplying the congenital superior sagittal sinus dural arteriovenous fistula (long arrows). Note the fenestration of the superior sagittal sinus (open arrow).

venous varices may also be identified. Although MRI can be used to document an occluded or stenosed dural sinus or vein,²⁶⁸ the evaluation can be problematic because of typically encountered variable venous signal intensity, caused by flowing blood within dural sinuses on various spin-echo pulse sequences, and the changing appearance of clot depending on its age. Other difficulties with MRI are the small caliber of the feeding arteries in dural arteriovenous malformations and the focal or diffuse rather than masslike site of the abnormal dural shunts, which are often

located next to flowing blood and near cortical bone making their distinction difficult. MR venography can be used to define patent, occluded, or stenotic dural sinuses.

Catheter cerebral angiography is always necessary for full evaluation of the angioarchitecture of cerebral AVFs.

Vein of Galen Malformations

The vein of Galen malformation is a congenital anomaly in which AVFs supply the embryologic precursor to the

vein of Galen. Some writers have divided vein of Galen malformations into two types, choroidal and mural. The choroidal type (Type I), which is more common, consists of one or more anterior and posterior choroidal, distal pericallosal, thalamoperforating, and sometimes superior cerebellar arteries directed to the dorsal vein of the prosencephalon, which continues into the median prosencephalic vein. With this type, the posterior choroidal vessels are typically the dominant supply. The mural type (Type II) of malformation consists of collicular and posterior choroidal arteries supplying the wall of the median prosencephalic vein, although additional arteries, such as the thalamoperforators, may also be contributors. These features distinguish the vein of Galen malformation from congenital parenchymal AVMs, acquired dural AVFs, and vein of Galen or straight sinus stenoses, which feature a dilated vein of Galen. The primitive median prosencephalic vein, the precursor of the vein of Galen, is usually abnormally dilated in vein of Galen malformations. Normal deep veins drain not into the median prosencephalic vein but through

alternate routes, because the true vein of Galen is absent. The persistent median prosencephalic vein drains to a falcine sinus rather than the straight sinus, and the straight sinus is often absent. Venous outflow restriction is common in the vein of Galen malformation and contributes to further dilatation of the median prosencephalic vein, also commonly referred to as a dilated vein of Galen. Other venous anomalies are often associated with the vein of Galen malformation, including absence of or hypoplastic sigmoid or jugular sinuses, duplicated sinuses, and persistent marginal or occipital sinuses.⁵⁹ Venous-to-arterial shunting through a patent foramen ovale or persistent ductus arteriosus may coexist.^{59a, 176, 191a}

The venous drainage of the enlarged median prosencephalic vein or vein of Galen typically demonstrates a dilated venous varix continuing into an accessory or inferior falcine sinus. If the venous outflow stenosis is severe enough, some Vein of Galen malformations have been documented to proceed to thrombosis which may lead to spontaneous cure but also can result in acute hydrocephalus.

Fig. 8-17. CT examination of a vein of Galen malformation before (A) and after (B) contrast. B, C, D, Note the enlarged primitive median prosencephalic vein (short arrow) continuing to the falcine sinus (long arrow). Both structure are dense without contrast in an infant. C and D illustrate numerous enlarged arteries supplying this choroidal type of vein of Galen malformation.

lus, intracranial hemorrhage, or central venous hypertension.

The extent of high-flow shunting and the amount of venous outflow restriction in a vein of Galen malformation determine the age of the patient at presentation. Patients with high-flow multiple fistulas and no venous outflow stenosis (usually type I) are often identified at birth with high-output congestive heart failure, intracranial bruit, macrocephaly, and hydrocephalus. If the vein of Galen shunt is severe enough, the infants can demonstrate metabolic lactic acidosis due to multiorgan hypoperfusion and quickly progress to death. Patients who have decreased flow through the a vein of Galen malformation, typically those with high-grade venous outflow restriction (usually type II), may present later in childhood, even as adults. In such patients, cardiomegaly may be asymptomatic, and developmental delay and ocular symptoms are more common. Seizures, enlarging head circumference, intracranial hemorrhage that may be parenchymal, subarachnoid, or intraventricular, focal neurologic deficit, pulsatile tinnitus, and cranial bruit can be seen in any patient with a vein of Galen malformation, although hemorrhage is rare and is usually seen only with venous drainage thrombosis.

CT and MRI

CT scans clearly demonstrate the enlarged primitive median prosencephalic vein, which appears as a mass in the tentorial incisura of slightly increased density on unenhanced scans and markedly enhances with use of an iodinated contrast agent (Fig. 8–17). Intravenous contrast administration also may demonstrate the feeding arteries as well as the disproportionate outflow restriction, which is often characterized by diffuse or focal narrowing of the falcine sinus or, less commonly, of the straight sinus. Unenhanced CT scanning is valuable for identifying brain parenchymal calcifications located in the hemispheric venous watershed zones owing to chronic deep venous hypertension.

MRI provides a 3D display of the vein of Galen malformation, documenting the dilated primitive median prosencephalic vein, the falcine sinus, and the abnormal arterial supply (Fig. 8–18). Flow-related artifacts are related to the size of and rate of flow through the vein of Galen malformation. MRA can also display the malformation.

MRI, CT, and ultrasonography can demonstrate brain parenchymal encephalomalacia, atrophy, hemorrhage, thrombosis, and ischemic changes. Each modality's efficacy depends on the patient's age at presentation and the corresponding degree of brain myelination or, in the case of ultrasonography, the size of the skull fontanels. Each imaging technique also accurately depicts hydrocephalus. The enlargement of the ventricular system is due to venous hypertension and impedance of CSF resorption (communicating hydrocephalus) or, less commonly, to obstruction of the aqueduct of Sylvius by the enlarged vein of Galen (obstructive hydrocephalus). In utero, hydrocephalus may produce cerebral developmental dysplasia.

Transcranial ultrasound examination in the fetus or neonate is often used to provide the initial diagnosis of vein of Galen malformations. Catheter cerebral angiography is

Fig. 8–18. Short TE, long TR axial MRI of a vein of Galen malformation. Note the enlarged vein of Galen (primitive median prosencephalic vein) (*long arrow*) producing flow artifact (*short arrows*). B, Sagittal T1-weighted MRI illustrates the vein of Galen malformation including the enlarged vein of Galen (primitive median prosencephalic vein) (*straight arrow*) and a low falcine vein (*curved arrow*). (Case courtesy of Michelle Smith, MD.)

necessary to define the angioarchitecture of the malformations and to correctly categorize it.

Vein of Galen malformations are typically treated with endovascular or combined operative transthoracic and endovascular methods.

Central Nervous System Trauma

John J. Wasenko
Leo Hochhauser

The neuroradiology of trauma has undergone dramatic changes since the advent of computed tomography (CT) and more recently with the establishment of magnetic resonance imaging (MRI) as a diagnostic imaging tool. With the ubiquitous availability of CT in the 1970s, the diagnosis and management of head trauma have changed significantly. Elaborate neurologic testing to appropriately localize a space-occupying lesion such as an intracerebral hemorrhage is no longer of paramount importance, because CT precisely defines the nature and location of the lesion, thus facilitating rapid implementation of treatment. Since the early days of CT scanning, when the contents of the skull were imaged noninvasively for the first time, CT has been the primary modality for evaluating patients with acute head injuries.^{1,52} The ability of CT scans to rapidly demonstrate a surgically correctable lesion, fracture, and subarachnoid hemorrhage (SAH) makes it the modality of choice in the evaluation of acute head injury. CT scans delineate acute hemorrhage from brain edema and allow one to determine whether a hematoma is intracerebral or extracerebral. Modern high-resolution CT scanning, with the direct display of axial anatomy, has replaced angiography as the prevalent method of demonstrating the indirect sign of intracerebral, epidural, or subdural hematomas (SDHs). Although the extent and multiplicity of lesions can be well evaluated by CT scans, MRI, with its greater sensitivity, frequently shows additional areas of contusion and shear injury.

MRI is playing an increasingly important role in the evaluation of head trauma. It has proved more sensitive than CT in the detection of diffuse axonal (shear) injury, nonhemorrhagic contusions, and SDHs and is equivalent to CT in the depiction of hemorrhagic contusions.^{37-39, 50, 136} The development of MRI-compatible life-support equipment, such as nonferromagnetic ventilators, allows the severely injured, comatose patient to be evaluated with MRI. The use of adequate sedation minimizes patient discomfort and motion, which may severely degrade image quality. Disadvantages of MRI that preclude its use in the evaluation of acute head injury include long scan time and the inability to detect fractures, SAH, and hyperacute hemorrhage. MRI is the modality of choice in the subacute and chronic stages of head injury because it is more sensitive than CT in the detection of both hemorrhagic and nonhemorrhagic lesions.

Technique Computed Tomography

Ten-millimeter scans without interslice gap are made at an angle of 15 to 20 degrees to the canthomeatal line and parallel to the skull base. To reduce beam-hardening artifacts and increase the conspicuity of small lesions, the posterior fossa may be studied with 5-mm slices from the C1 arch, through the level of the posterior clinoids, followed by 10-mm slices from the sella through the vertex. From the array of image-processing algorithms, the one specially designed for soft tissue densities or a combination of soft tissues and bone is best suited for making a diagnosis and establishing appropriate management in the acute trauma situation. Algorithms for high spatial resolution imaging are necessary for trauma to regions with great density differences such as the face (air-soft tissue and air-bone interfaces), the skull base and the temporal bone, and occasionally, the cranial vault.

We frequently use the intermediate algorithm ("Detail," GE; "High," Siemens; "Soft," Picker) because it provides good resolution for soft tissues, gives excellent resolution for edema and hemorrhage, and defines fractures well without blooming artifact from bone (which often occurs with the soft tissue algorithms). Therefore, this algorithm is particularly well suited to image associated facial injuries in which density differences range from air to bone densities. Specific algorithms for bone densities are well suited to examine fracture sites of the facial bones, skull base, and cranial vault.

Hard copies are printed in the following three different window settings to allow for routine viewing of three different areas of interest: (1) the soft tissues of the brain for infarct or hemorrhage, (2) the extracerebral spaces to detect hematomas adjacent to the dense bone of the skull vault and skull base, and (3) the bones for the detection of fractures. Intravenous contrast agent usually not required. If, however, there is unexplainable mass effect or the study is normal but the patient is comatose or lethargic or presents with a focal neurologic deficit, the administration of intravenous contrast material may become necessary. Often, MRI, with its inherent greater sensitivity, may be required for these patients. Small SDHs are difficult to visualize with CT, whereas they pose no difficulty with MRI. Isodense SDHs can usually be visualized with current third- and fourth-generation CT imaging equipment. Intravenous contrast agents may facilitate their detection by

increasing the density of the cortical vessels, thus creating a density interface between blood and the diffusely enhancing cortex or cortical vessels, which are displaced from the inner table of the skull.

Axial CT scans performed with current high image resolution scanners provide exquisite image detail and are usually sufficient in the emergency situation. Imaging in the coronal plane is frequently better for the evaluation of fractures of the skull base but may not be feasible because of the patient's condition. Coronal reconstructions are adequate only when thin slices (≤ 3 mm) are used, but they usually lack the rich detail of direct coronal scans.

Magnetic Resonance Imaging

Conventional T1- and T2-weighted spin-echo (SE) images are used in the evaluation of head trauma. Proton-density and T2-weighted sequences are sensitive in the detection of nonhemorrhagic lesions such as contusions and diffuse axonal (shear) injury, because of the sensitivity of these sequences to the presence of extracellular free water. The T2-weighted sequences are also sensitive in the detection of acute and chronic hemorrhage, especially at high field strength (1.5 T).⁴⁴ The use of T1-weighted sequences readily allows the detection of subacute hemorrhagic lesions. Acute hemorrhagic lesions are poorly seen on T1-weighted images because they are isointense or slightly hypointense. Conventional SE sequences may be supplemented with T2* gradient-recalled echo (GRE) sequences, which are highly sensitive in the detection of small acute and chronic hemorrhagic lesions.^{3, 28} Fast spin-echo (FSE) sequences may be used in place of conventional SE sequences, resulting in much faster scan time, which is an important consideration in critically injured patients. FSE sequences offer similar lesion conspicuity in the visualization of nonhemorrhagic lesions.⁵⁸ Magnetic susceptibility effects are less evident on FSE images, and as a result, hemorrhagic lesions are not as hypointense as with SE sequences. Although the hemorrhagic lesions are not as hypointense on FSE images, they are still evident and almost equivalent to that noted on SE images.⁵⁷ The multiplanar imaging capability and superior contrast resolution of MRI are advantages over CT in that they allow the accurate localization and characterization of intracranial injuries.³⁹ Sagittal T1-weighted and axial T2-weighted sequences supplemented with a T2* GRE sequence enable the detection and localization of both nonhemorrhagic and hemorrhagic lesions.

Image parameters for T1-weighted images (TR = 500 msec, TE = 20 msec, 2 excitations), for proton-density images (TR = 2000 msec, TE = 30 msec, 1 excitation), and for T2-weighted images (TR = 2000 msec, TE = 80 msec, 1 excitation) achieve a high enough signal-to-noise ratio to allow the detection of small lesions. T2* GRE image parameters (TR = 500 to 700 msec, TE = 20 to 25 msec, flip angle 15 to 20 degrees) provide sufficient sensitivity to magnetic susceptibility effects. FSE proton-density (TR = 2500 msec, TE = 17 msec, 1 excitation), echo train 4 sequences and T2-weighted (TR = 3500 msec, TE = 102 msec, 1 excitation), echo train 8 sequences, acquired separately, may be used in place of conventional SE sequences with a decrease in scan time.

Images with higher signal-to-noise ratio, contrast, and spatial resolution values may also be obtained in a comparable scan time with the use of more excitations. A 5-mm slice thickness with a 2.5-mm gap and a 256×192 matrix provides adequate signal-to-noise ratio and spatial resolution.

Fractures

Demonstration of a fracture on skull radiographs indicates that a significant force has been applied to the bony vault. However, the lack of visualization of a fracture does not exclude significant injury to the underlying brain. CT evaluation of the skull and brain has therefore superseded the primary evaluation with skull films. In the emergency room assessment of a trauma victim, the primary concern is the diagnosis of injury to the brain and life-threatening post-traumatic changes of intracranial hemorrhage and vascular spasm. Fractures may involve the skull vault, the skull base, or both.

Linear Fracture

Linear fractures that run parallel in the axial plane are easily missed on CT scans, and are usually negligible if no associated brain injury is demonstrated (Fig. 9-1).

Depressed Fracture

A fragment is considered depressed when its outer table is displaced below the level of the inner table of the skull (Fig. 9-2). Although skull films are frequently diagnostic,

Figure 9-1. Axial CT scan with bone window setting shows nondepressed fractures of the right temporal bone (arrows).

Figure 9-2. Depressed fracture with fragment of the left frontal bone (arrow).

the depression can usually be identified during CT on the preliminary computer generated scout image of the skull. Depressed fractures near the vertex or the skull base require direct coronal imaging or reconstructions in a plane parallel to the vector of impact. Delineation of a depressed fracture is important because it may be the cause for an underlying dural tear, extracerebral hematoma, or brain contusion. Although compound depressed fractures frequently require surgical treatment, the majority of such injuries are managed conservatively. The goals of treatment are the prevention of infection and post-traumatic epilepsy and the amelioration of neurologic deficits.¹²⁵ Depressed fractures adjacent to venous sinuses are usually left in place because of the danger of uncontrollable hemorrhage when fragments are removed.

Basilar Skull Fracture

If a basilar skull fracture is clinically suspected, high spatial resolution CT scans with a thickness of 3 mm or less are required to delineate a fracture of the chondrocranium. Alternatively, CT scans may suggest a basilar skull fracture before it becomes clinically evident. An air-fluid level in the paranasal sinuses or the mastoid air cells should be viewed as secondary to a basilar skull fracture until proven otherwise.

Frontal Sinus Fracture

It is important to visualize fractures of the posterior wall of the frontal sinus because they frequently require surgical

closure of the disrupted dura to prevent cerebrospinal (CSF) leakage and infection. Some surgeons treat only the severely comminuted fracture or when there is overt CSF leakage or pneumocephalus, and “simple” comminuted fractures are treated conservatively.¹²⁵ Fractures of the cribriform plate are commonly associated with anosmia.

Pneumocephalus

Air locules in the extracerebral spaces usually indicate traumatic air entry resulting from fracture of a paranasal sinus or mastoid air cells abutting the dura (Fig. 9-3). When associated with a dural tear, they may be complicated by CSF leakage, empyema, meningitis, or brain abscess. Most post-traumatic CSF leaks cease spontaneously, and the responsible fractures may never be visualized.¹²³

Growing Fracture

Enlarging skull fractures have been described in 0.75% of skull fractures in children. Most cases are associated with a history of significant trauma, such as experiencing a motor vehicle accident, being struck by a train, or falling out of a window, that causes a skull fracture and contusion of the underlying brain. Growing fractures commonly occur in the growing skull, although occasional reports of such lesions in adults are on record.⁷¹ The ongoing normal growth of the child's brain is considered an aggravating factor.¹²⁶ Children with growing fractures present weeks to

Figure 9-3. Pneumocephalus. Collections of air overlie the frontal lobes and extend along the anterior interhemispheric fissure (arrows).

years after injury with a pulsatile mass or rarely with a depressed calvarial defect.⁷⁵ Kingsley and coworkers reported 10 cases in children seen over 10 years.⁶⁴ The lesions seem to occur when a skull fracture in childhood is accompanied by a dural tear or rent, with focal protrusion of the arachnoid membrane into the fracture gap. The unabating CSF pulsations transmitted to the entrapped

arachnoid protrusion result in the remodeling of bone of the growing skull at the fracture site, causing enlargement of the fracture line (Fig. 9–4). The frequently underlying porencephaly or encephalomalacia appears to be the result of an associated contusion from the initial trauma rather than the pathogenetic factor in the enlargement of the fracture. The term “leptomeningeal cyst” is obsolete.^{54, 71}

Figure 9–4. A, Growing fracture. Unenhanced CT can shows a defect in the left parietal bone (arrow). B and C, Axial T1-weighted (500/15) and T2-weighted (2500/80) MR images reveal mass isointense with CSF (arrows). D, Coronal enhanced T1-weighted (500/15) image shows no enhancement of lesion (arrow).

Figure 9-5. A and B, Cephalhematoma. CT scans with soft tissue and bone windows show partially ossified cephalhematoma overlying the right parietal bone. Note remodeling of the underlying parietal bone. Soft tissue swelling is present, overlying and posterior to the cephalhematoma.

Cephalhematoma may occur as a result of a difficult labor and delivery. A shell of cortical bone forms around the periphery of a subperiosteal hematoma, which may result in deformity of the calvarium (Fig. 9-5).

Intracerebral Hematoma

Intracerebral hematomas are differentiated from hemorrhagic contusions in that the former are homogeneously hyperdense, sharply margined, and surrounded by a rim of decreased density (Fig. 9-6).⁶⁶ Considerable mass effect may be present, depending on the size of the lesion. The most common sites of involvement are the frontal and temporal lobes.^{66, 132} Other rare sites of involvement are the basal ganglia and posterior fossa.^{60, 119} Hematomas may be bilateral or multiple and are frequently associated with other lesions, such as SAH and SDHs.^{26, 66, 132} Not infrequently there is associated rupture of the hematoma into the ventricular system.¹³²

Intracerebral hematomas occur most commonly at the time of injury; however, they may be delayed, with most appearing within 48 hours following head injury.⁷³ Rarely an intracerebral hematoma appears several weeks after the episode of trauma. Possible etiologies of a delayed intracerebral hematoma include focal loss of autoregulation in an area of brain contusion and surgical evacuation of a lesion such as an SDH with relief of a tamponade effect and subsequent hemorrhage into the area of traumatized brain.⁷³

Intracerebral hematomas demonstrate a typical pattern of evolution as blood products are gradually broken down

Figure 9-6. Intracerebral hematoma. Large, well-margined hematoma in the right parietal lobe with rupture into the ventricular system.

and resorbed.⁸² Initially the intracerebral hematoma is hyperdense from clotted blood with surrounding edema and mass effect. Enhancement may be evident within or around the hematoma with the administration of intravenous contrast material.¹²⁰ The hematoma gradually becomes isodense with brain parenchyma over several weeks to a month.^{23, 82} Mass effect persists after the hematoma has become isodense because the decrease in mass effect does not occur simultaneously with decrease in the density of the hematoma.^{23, 82} At this time, the hematoma exhibits ringlike enhancement from the surrounding capillary proliferation.¹²⁰ Decreased density eventually appears over 1 to several months. Encephalomalacia is evident as low density with adjacent sulcal enlargement and ventricular dilatation.

The MRI appearance of intracerebral hematoma has been described at low and high field strengths.^{21, 25, 44, 110, 137} The following description of the evolution of intracerebral hematomas is at a field strength of 1.5 T.^{44, 45} *Acute hematomas* are less than 1 week old, *subacute hematomas* are more than 1 week and less than 4 weeks old, and *chronic hematomas* are more than 1 month old. Acute hematomas are isointense or slightly hypointense on T1-weighted images and very hypointense on T2-weighted images. The extreme hypointensity is caused by preferential T2 proton relaxation enhancement (PRT2PRE) of intracellular deoxyhemoglobin, which is dependent on the square root of the magnetic field strength and the interecho interval. The PRT2PRE phenomenon is caused by the dephasing of water protons in areas of local magnetic field inhomogeneity. As the echo time lengthens, signal loss increases as water protons experience the local field inhomogeneity for a

longer period. Acute hemorrhage is therefore slightly hypointense on a proton-density-weighted image and very hypointense on a T2-weighted image.

Subacute hematomas have a variable appearance at high field strength.⁴⁵ The hematoma in the subacute state is composed of methemoglobin, a paramagnetic material. Paramagnetic materials produce T1 and T2 shortening, which theoretically results in hyperintensity on T1-weighted images and hypointensity on T2-weighted images. The concentration of methemoglobin, however, determines the signal intensity present on any image sequence. Concentrated (undiluted) intracellular methemoglobin acts as a true paramagnetic material and appears hyperintense on T1-weighted images and very hypointense on T2-weighted images. Undiluted extracellular methemoglobin is hyperintense on T1-weighted images and slightly hypointense on T2-weighted images. Dilute extracellular methemoglobin is hyperintense on both T1- and T2-weighted images (Fig. 9-7). The mechanism of relaxation for methemoglobin is proton-electron dipole-dipole relaxation enhancement (PEDDRE). The hyperintense signal is present initially at the periphery of the hematoma and gradually progresses toward the center of the hematoma. Chronic hematomas are isointense to slightly hypointense on T1-weighted images and very hypointense on T2-weighted images because of the presence of hemosiderin. The signal intensity of the chronic hematoma is similar to that of acute hematoma because of a similar mechanism of relaxation—PRT2PRE.

GRE acquisition imaging is highly sensitive to the detection of acute and chronic hemorrhage,^{3, 28, 103, 122} because

Figure 9-7. A and B, Right frontal lobe subacute intracerebral hematoma is hyperintense on sagittal T1-weighted (500/15) and axial T2-weighted (2500/80) MR images. The hyperintensity reflects the presence of dilute intracellular methemoglobin. Note the right convexity subacute subdural hematoma.

of the sensitivity of GRE sequences to the magnetic susceptibility effects of acute and chronic hemorrhage.²⁸ Hemorrhagic lesions are more evident, and more are detected with GRE than with conventional SE sequences.³¹ The conspicuity of hemorrhagic lesions on SE sequences is superior at 1.5 T than at 0.5 T. The addition of a GRE sequence at lower field strength provides depiction of a hemorrhagic lesion equal to that obtained at higher field strength.¹⁰³

The development of FSE sequences results in decreased scan time and motion artifact. Lesion conspicuity with FSE sequences is similar to that obtained with SE sequences.⁵⁸ FSE sequences are, however, less sensitive in the detection of hemorrhage because they are not as sensitive to magnetic susceptibility effects as conventional SE sequences.⁸⁰ Despite the relative lack of sensitivity of FSE sequences to the presence of hemorrhage, they are comparable to SE sequences in hemorrhage detection.⁵⁷ The addition of a GRE sequence allows the detection of small foci of hemorrhage that may not be visualized on FSE images.

Epidural Hematoma

Epidural hematomas are characteristically biconvex or lentiform (Fig. 9–8).²⁵ Uncommonly, epidural hematomas may be bilenticular, crescentic, or irregular.¹⁹ The shape is determined by the dura, which is firmly adherent to the inner table of the skull. A blow to the calvarium results in damage to the underlying vessel, with subsequent displacement of the dura away from the inner table of the skull. The vessel may be damaged, even without fracture of the adjacent bone, as is commonly seen in children. Fracture of the adjacent bone is, however, common.¹²⁸ The most

Figure 9–8. Typical biconvex epidural hematoma is present over the right parietal lobe.

Figure 9–9. Heterogeneous left temporal convexity epidural hematoma exhibits considerable mass effect. Heterogeneous areas represent unclotted blood.

common location for epidural hematomas is over the temporal lobe, followed by the parietal, frontal, and occipital lobes with the posterior fossa the least common location.¹⁹ Damage to the middle meningeal artery is responsible for most epidural hematomas; however, they may occur as a result of laceration of diploic veins or dural sinuses.¹²⁸

Epidural hematomas may be classified as acute, subacute, and chronic. An acute epidural hematoma is heterogeneous in attenuation, containing areas of hyperdense blood and isodense serum (Fig. 9–9). Subacute epidural hematoma is homogeneously hyperdense in attenuation, consisting of solid blood clot (Fig. 9–10). Heterogeneous or decreased attenuation, as well as an enhancing membrane, are characteristics of chronic epidural hematoma, as a result of degradation of blood products.¹²⁸ Peripheral enhancement representing dura and membrane formation between the epidural hematoma and adjacent brain parenchyma may be seen in chronic epidural hematomas with the use of intravenous contrast.⁹⁰ Delayed epidural hematoma is most commonly from slow venous bleeding from rupture of a dural sinus (Fig. 9–11).^{54, 90, 110} Other causes of delayed epidural hematoma are pseudoaneurysm rupture of an epidural vessel and arteriovenous fistula.⁸⁴ In some instances, when minimal neurologic signs and symptoms are present, epidural hematoma may undergo spontaneous resolution, which is visualized on serial CT scanning.¹²⁴ Some hematomas expand 1 to 2 weeks after injury and then gradually resolve. This expansion correlates with an increase in or persistence of symptoms.⁹² The imaging

Figure 9-10. Right temporal convexity epidural hematoma is largely homogeneous in density, indicating the presence of clotted blood. Note the effacement of the basal cisterns (arrowheads).

criteria in determining whether an epidural hematoma may be treated conservatively are (1) a diameter of less than 1.5 cm and (2) a minimal midline shift of less than 2 mm. The patient must be neurologically intact without focal deficit.^{48,104} Parenchymal abnormalities are not present as frequently with epidural hematomas as with acute SDHs. Surgical evacuation of the hematoma results in marked clinical improvement. Little or no residual hematoma is evident on postoperative scans.²⁴

Posterior fossa epidural hematomas are rare; however, delay in detection may result in fatal brain stem injury.¹¹⁹ Many posterior fossa epidural hematomas are not readily visualized on CT because of beam-hardening artifact. The use of contrast material facilitates the detection by demonstrating displacement of the dural sinuses, the torcular herophili, or both as well as displacement of the dura away from the calvarium.¹¹⁹

MRI studies allow the distinction between epidural hematomas and SDHs, which may not be possible with CT scans when a hematoma is small or is not typically biconvex. In epidural hematomas, the dura is seen as a curvilinear band of decreased signal intensity between the hematoma and brain parenchyma (Figs. 9-12 and 9-13).³⁹ Venous epidural hematomas may be differentiated from arterial hematomas on the basis of the former's proximity to a dural sinus and displacement of the involved sinus away from the inner table of the skull.^{36, 84} The majority of posterior fossa epidural hematomas are of venous origin and may not be well visualized with CT scans because of beam-hardening artifact from adjacent bone structure.¹²⁸

Figure 9-11. Delayed epidural hematoma. A, Acute subdural hematoma is present over the left parietal convexity (arrowheads). Note the small hemorrhagic contusion in the left parietal lobe. B, The patient has undergone craniectomy and drainage of the subdural hematoma. Note the new posterior parieto-occipital epidural hematoma (arrowheads).

Figure 9-12. A and B, Sagittal T1-weighted (500/15) and axial T2-weighted (2500/80) MR images show large subacute epidural hematoma overlying the left frontal lobe. Note the displacement of the hypointense dura away from the inner table of the calvarium (arrowheads).

Figure 9-13. A and B, Subacute right temporal convexity epidural hematoma is hyperintense on both sagittal T1-weighted (500/15) (arrow) and axial fast spin-echo T2-weighted (4000/108) MR images (arrowheads). The band of hypointensity corresponds to the displaced dura (arrowheads). Retention cyst is present in the sphenoid sinus.

The lack of artifact from bone on MRI studies readily enables the detection of a small epidural hematoma.

Subdural Hematoma

SDHs are most commonly caused by shear forces that result in the tearing of the bridging veins present in the subdural space.³⁵ Laceration of cortical arteries and parenchymal contusions are other causes of SDHs.¹⁰⁵ Rarely, an SDH may be caused by rupture of an aneurysm or arteriovenous malformation.⁹⁶ Unlike an epidural hematoma, which is focal, an SDH is diffuse and may overlie an entire cerebral hemisphere. The potential subdural space offers little or no resistance to the expansion of the hematoma within the subdural space.

Underlying brain injury, such as hemorrhagic contusion and edema, are frequently seen with acute SDH.^{26,132} These injuries are seen more commonly with SDH than with epidural hematoma.²⁴ The degree of mass effect seen with SDH is often out of proportion to the size of the hematoma. This mass effect is from the presence of hemorrhagic contusions and edema rather than the SDH.^{24,132}

The typical appearance of an acute SDH is a hyperdense crescent-shaped collection with a convex lateral border and concave medial border overlying the cerebral convexity (Fig. 9-14).^{26,132} Occasionally the hematoma may be biconcave, simulating the appearance of an epidural hematoma.¹² This biconcavity can be seen particularly when the hematoma is large.³⁴ The majority of acute SDHs are hyperdense because of the attenuating properties of the hemoglobin molecule. In one report, SDHs were found to be hyperdense in all patients with a history of acute injury.¹⁰² An

acute SDH may be isodense with brain parenchyma in patients with anemia as a result of a reduced concentration of hemoglobin.¹¹³ The typical acute SDH gradually approaches the density of brain parenchyma and appears isodense with brain over an interval of 1 to 5 weeks.²⁶ This change occurs from the breakdown and absorption of blood products.

The classic homogeneous, hyperdense appearance of acute SDH is not always present. The hematoma may appear mixed rather than homogeneous in attenuation.⁹⁵ It may have one of three patterns: marginal hypodensity, central irregular areas of hypodensity, or laminar areas of hypodensity (Figs. 9-15 and 9-16). The low density may be secondary to unclotted blood or possibly CSF resulting from arachnoid tears. The mixed SDH is usually larger and has more mass effect than the classic hyperdense SDH.

SDHs located adjacent to the tentorium may simulate an intra-axial lesion. Several features serve to distinguish the subdural location of the lesion. Supratentorial SDHs located adjacent to the tentorium have a well-defined medial margin corresponding to the edge of the tentorium. A sheetlike area of increased density that slopes laterally is present, and the trigone of the lateral ventricle is rotated anteriorly and superiorly.⁶⁹ When the hematoma is located below the tentorium, the lesion has a sharp lateral margin corresponding to the tentorium and increased density that slopes medially (Fig. 9-17).

Interhemispheric SDHs occur in the posterosuperior aspect of the interhemispheric fissure (Fig. 9-18).¹³⁵ Anterior extension of the lesion occurs less commonly. This lesion may be differentiated from a normal or calcified falx and SAH. SDH in the interhemispheric location has a character-

Figure 9-14. A, Crescentic right convexity acute subdural hematoma is evident from the irregular contour on the brain window setting. B, The subdural hematoma is better demonstrated with an intermediate window setting.

Figure 9-15. Acute left convexity subdural hematoma has marginal hypodensity, representing unclothed blood or cerebrospinal fluid.

Figure 9-16. Irregular areas of hypodensity indicate that unclothed blood or cerebrospinal fluid is present in this acute left convexity subdural hematoma.

Figure 9-17. A, It is difficult to localize this ill-defined subdural hematoma (arrow). B, Coronal reconstruction localizes the hematoma to the infratentorial space by its smooth-appearing superior border (arrow).

Figure 9-18. Interhemispheric subdural hematoma. The flat medial border of this acute hematoma localizes it to the subdural space above the tentorium.

istic crescentic shape with a flat medial border that abuts the falx and a convex lateral border that abuts the brain. The hematoma is located posterior and superior to the splenium of the corpus callosum. When anterior extension is present, the hyperdensity extends inferiorly in the subdural space to the termination of the falx, which is superior to the genu of the corpus callosum. It can be differentiated from SAH that occurs in the anterior interhemispheric fissure, which has a zigzag configuration conforming to the cortical sulci. In children, increased density along the falx represents SAH because falx calcification rarely occurs in this age group.²² The SAH extends from the calvarium inferiorly to the rostrum of the corpus callosum, differentiating it from an SDH. Posterior fossa SDHs are rare lesions.¹¹⁹ Distinction between SDHs and epidural hematomas may be accomplished with the use of intravenous contrast agents that allow differentiation between the two lesions.¹¹⁹

Postoperatively, residual SDH may be seen from failure to find the origin of bleeding and difficulty in removing blood clot adherent to the arachnoid (Fig. 9-19).³¹ Small SDHs are not surgically evacuated and are managed by observation. These lesions are gradually resorbed over time as fibrinolysis and absorption of blood clot occurs.⁵

The majority of SDHs differ in attenuation from adjacent brain, being either hyperdense or hypodense relative to brain, and are readily diagnosed with CT scanning. Isodense SDHs—with attenuation values near or equal to those of brain parenchyma—may be difficult to diagnose. As blood products become degraded, a hyperdense SDH

gradually decreases in attenuation, becoming isodense with brain. Occasionally, rebleeding into a chronic SDH results in an isodense lesion.²⁶ Acute isodense SDH may rarely be seen, occurring in patients with anemia.¹¹³ Other possible causes of isodense SDH are dilution with CSF secondary to arachnoidal tear and local or disseminated coagulopathy.^{8, 61}

Effacement of the cortical sulci over the cerebral convexity and mass effect on the ventricular system or midline shift indicate the presence of an isodense SDH (Fig. 9-20).² Mass effect on the ventricular system may be negligible or absent when bilateral collections are present.³⁴ Delayed contrast-enhanced CT scans performed 4 to 6 hours after injection of the contrast agent reveal enhancement of the subdural collection.^{2, 82} Contrast-enhanced CT scans may also demonstrate enhancement of cortical veins that are displaced medially from the inner table of the calvarium; however, this enhancement is not seen in all cases.⁶³ The use of rapid high-dose contrast enhancement allows the more accurate detection of an isodense SDH.⁴⁹ The majority of patients with an isodense SDH may have three or four of the following signs: posterior displacement of the ipsilateral anterior horn of the lateral ventricle, compression of the ipsilateral posterior and temporal horns, anterior displacement of the ipsilateral posterior and temporal horns, anterior displacement of the ipsilateral glomus calcification, and widening of the contralateral ventricle.⁸⁵ In a patient with a history of head trauma, the presence of small compressed ventricles with the absence of cortical sulci should raise the possibility of bilateral isodense SDH.⁶³ High-resolution CT scans allow the differentiation of gray matter from white matter. The presence of an extra-axial mass displaces the gray-white matter interface medially, producing buckling of the central white matter.⁴⁰ Buckling of the white matter is virtually diagnostic of an extra-axial mass (see Fig. 9-20).

Chronic SDHs are most commonly caused by trauma; however, the traumatic episode is frequently so minor that it is forgotten or ignored.^{16, 59} The chronic SDH is caused by a torn bridging vein in the subdural space through which venous blood slowly flows.²⁴ In one series, no acute SDH evolved into a chronic SDH.²⁴

Chronic SDHs are most commonly hypodense on CT scans (Fig. 9-21).⁶⁶ They are typically crescentic, however, they may be biconcave or lentiform as a result of fluid absorption into the hematoma.³⁴ Another possible cause is the formation of adhesions. A capsule composed of a capillary-rich membrane develops and surrounds the SDH.⁵⁹ This capillary-rich membrane is responsible for repeated episodes of rebleeding and subsequent increase in size of the hematoma. As the hematoma enlarges, the patient becomes symptomatic, showing signs of increased intracranial pressure, hemiparesis, or intellectual and personality change.¹⁶ Repeated episodes of rebleeding may result in a mixed-density collection containing areas of hypodense, isodense, and increased attenuation (Fig. 9-22). A chronic SDH may appear hyperdense from acute hemorrhage, simulating an acute process.^{26, 102} Fluid-fluid levels may be seen as blood products settle in the dependent aspect of the subdural collection, which becomes hyperdense relative to the superior aspect. Enhancement of the SDH may be seen on delayed CT scans obtained 3 and 6

Figure 9-19. A, Acute subdural hematoma is present over the right cerebral convexity with extension into the interhemispheric fissure posteriorly. B, Postoperative scan reveals small residual hematoma (arrow).

Figure 9-20. A, Left convexity isodense: subdural hematoma causes mass effect on and shift of the left lateral ventricle. B, White matter buckling (arrows) indicates the presence of the extra-axial subdural collection.

Figure 9-21. Bilateral frontal convexity chronic subdural hematomas are present. Note the slight shift of the septum pellucidum to the right.

Figure 9-22. Large chronic subdural hematoma overlies the left cerebral convexity. The hyperdense area represents recurrent hemorrhage (*long arrow*). Note the septations within the hematoma (*small arrows*).

hours after intravenous administration of contrast material.⁵⁹

A subdural hygroma is a hypodense extracerebral collection equal in density to CSF (Fig. 9-23). The lesions are crescentic and may be bilateral. It is not possible to distinguish a subdural hygroma from a chronic SDH with CT scanning, because the two lesions are identical in appearance. At surgery, clear fluid and lack of a membrane allow the diagnosis of a subdural hygroma.^{51,102}

The MRI appearance of SDH has been well documented.^{33, 86,111} In the acute phase (<1 week old), an SDH is isointense or slightly hypointense relative to gray matter on T1-weighted images and very hypointense on T2-weighted images. Early subacute hematomas (>1 one week and <2 weeks old) are characterized by a rim of hyperintensity surrounding a center of hypointensity on T1- and T2-weighted images. In the late subacute hematoma (>2 weeks and <1 month old), the lesion is hyperintense on both T1- and T2-weighted images (Fig. 9-24). Chronic SDH (>1 month old) are isointense relative to gray matter on T1-weighted images and hyperintense on T2-weighted images (Fig. 9-25). Usually no hypointensity is evident in chronic SDHs on T2-weighted images, most likely because of the lack of a blood-brain barrier and resorption of hemosiderin from the collection. Occasionally hemosiderin may be seen in thickened membranes and areas of rehemorrhage. Fluid-fluid levels of different signal intensity suggest rebleeding. It is possible to distinguish a chronic subdural hygroma from a chronic SDH because the hygroma is of CSF signal intensity on all pulse sequences (Fig. 9-26).³³

Figure 9-23. Cerebrospinal fluid-density collection representing a cerebrospinal fluid hygroma is present over the right frontal convexity (*arrows*). The initial CT scan 3 days earlier showed no subdural collection.

Figure 9-24. A and B, Sagittal T1-weighted (500/15) and axial T2-weighted (2500/80) MR images demonstrate hyperintense left frontal convexity subacute subdural hemorrhage. Right frontal convexity subacute hematoma is seen on the axial T2-weighted image (small arrows).

Figure 9-25. A and B, Right frontal convexity chronic subdural hematoma is slightly hyperintense on sagittal T1-weighted (500/15) and isointense on axial T2-weighted (2500/80) MR images relative to cerebrospinal fluid (arrows). Note displacement of the subdural veins away from inner table of the calvarium (arrowheads). A small left frontal convexity subdural hemorrhage is present.

Figure 9-26. A and B, Same case as shown in Figure 6-23. Sagittal T1-weighted (500/15) and axial fast spin-echo/T2-weighted (3500/108) MR images show cerebrospinal fluid hygroma over right frontotemporoparietal convexity (arrows). The small left frontal convexity hygroma not evident on the CT scan is well visualized on the MRI study (small arrows). Note the right temporal lobe contusion and herniation of the temporal lobe through the temporal bone fracture (black arrow).

It is not always possible to distinguish a subdural hygroma from atrophy because the findings of mass effect and sulcal effacement associated with subdural hygroma may be subtle. Visualization of cortical veins adjacent to displaced cortex is indicative of subdural hygroma. A diagnosis of atrophy is made when cortical veins are seen traversing a widened subarachnoid space.⁷⁹

Subarachnoid Hematoma

SAH is frequently present in the acutely injured patient. It is often associated with other lesions, such as intracerebral hematoma. SAH is caused by damage to blood vessels on the pia-arachnoid. Intraparenchymal hematoma with rupture into the ventricular system may gain access to the subarachnoid space via the foramina of Mangendie and Luschka. On CT scans, hyperdensity representing acute hemorrhage is visualized in the sulci overlying the cerebral convexities, within the sylvian fissures, basal cisterns, and interhemispheric fissure (Fig. 9-27). Hemorrhage is rapidly cleared from the subarachnoid space. The majority of CT scans performed within 1 week appear normal.⁶⁶

CT is the modality of choice in the evaluation of SAH because of the hyperdensity of clotted blood. It is difficult to visualize with MRI studies because the high oxygen concentration in CSF prevents the degradation of oxyhemoglobin to deoxyhemoglobin.^{10, 21, 39} This process has been described in detail in both clinical and experimental situations.^{10, 17} SAH may be seen on MRI studies only when large volumes of clot are present.³⁹ Acute SAH is isointense

Figure 9-27. Subarachnoid hematoma is present along the interhemispheric fissure. Blood in the sulci is responsible for the zigzag appearance of the interhemispheric hemorrhage. Hemorrhagic contusion is present adjacent to the falx in the left frontal lobe (arrowhead).

Figure 9-28. A, Acute subarachnoid hemorrhage in pontine cistern is isointense on axial T1-weighted (500/15) MR image (arrows). B, Hypointense hemorrhage is poorly seen on axial fast spin-echo T2-weighted (3900/108) image (arrows) because it is masked by hyperintense cerebrospinal fluid.

on T1-weighted images and hypointense on T2-weighted images with respect to brain (Fig. 9-28). Toward the end of the first week, the SAH exhibits T1 shortening and appears hyperintense on T1-weighted images.¹⁰ Subacute SAH does not evolve like intraparenchymal hematoma, which as stated previously becomes isointense or slightly hypointense on T1-weighted images and very hypointense on T2-weighted images in the chronic stage. This may be from the high oxygen concentration of CSF, which may prevent the further degradation of methemoglobin to hemosiderin, or from CSF pulsation, which may aid in clot dissolution and resorption. The residual of SAH may be evident as hypointensity in the leptomeninges because of hemosiderin deposition present in macrophages.⁴³ This reflects the preferential T2 shortening that occurs as water protons precess through a local heterogeneous magnetic field and lose signal intensity. The effect is more evident at high field strength.⁴⁴ A T2* GRE sequence with a short flip angle and relatively long TE has been utilized in the improved detection of intraparenchymal hemorrhage.^{28, 122} The improved ability of these sequences to detect hemorrhage stems from their sensitivity to inhomogeneities in the magnetic field that are produced by paramagnetic blood products. The use of GRE sequences may allow improved detection of acute SAH. Fast fluid-attenuated inversion recovery (FLAIR) sequences have proved to be sensitive in the detection of SAH. It is, however, nonspecific as leptomeningeal carcinomatosis and meningitis can have a similar appearance.^{109a}

Contusion

Contusions are the most commonly encountered lesions due to head trauma.^{26, 66, 130} The lesions are characterized

pathologically as areas of hemorrhage, necrosis, and edema. The mechanism of contusion production is complex and depends on many factors, with lesions occurring at the site of impact as well as at sites remote from impact; they are referred to as coup and contrecoup lesions, respectively. A *coup* lesion is produced by transient inbending of the calvarium with resultant compression of the underlying brain. Fracture of the calvarium is not always present. The *contrecoup* lesion is produced when the calvarium decelerates but the brain continues in motion and strikes the irregular inner surface of the calvarium.⁴⁶

Contusions appear as areas of heterogeneous increased density mixed with or surrounded by areas of decreased or normal density (Figs. 9-29 to 9-31).^{26, 66, 130, 132} Mass effect may or may not be present, depending on the size of the lesion. The frontal lobe convexity and the lateral temporal areas are the most common sites for coup injury.¹³⁰ Contrecoup injuries typically involve the inferior surface of the frontal and temporal lobes.¹³⁰

Hemorrhagic contusions have a typical pattern of evolution that occurs over several months.¹³⁰ The initial area of heterogeneous increased density progresses to an area of decreased density within 1 week. At 2 weeks, the contusion is not visualized because it is isodense with brain parenchyma. Enhancement occurs during the acute and subacute stages.^{120, 130} Focal encephalomalacia becomes evident by 1 month after injury. Contusions may be isodense if they consist of equal amounts of hemorrhage and edema. The use of intravenous contrast material allows the detection of these isodense lesions as contrast material accumulates in areas of blood-brain barrier breakdown.^{117, 120}

In the posterior fossa, contusions may be difficult to detect because of beam-hardening artifact from adjacent

Figure 9-29. A, Hemorrhagic contusions with surrounding edema are evident in the inferior left frontal and anterior right temporal lobe (arrowheads). B, CT scan at higher level reveals additional cortical hemorrhagic contusions in the frontal lobe (arrowheads).

Figure 9-30. Axial CT scan demonstrates multiple hemorrhagic contusions in the temporal lobes. Note the small left occipital lobe convexity subdural hematoma (arrow).

Figure 9-31. Deep gray matter contusion. Hemorrhagic contusion involves the right lentiform nucleus (arrow).

bony structure (Fig. 9–32). In some instances, no lesion can be identified, and the presence of indirect signs such as effacement of the pontine, cerebellopontine angle, and perimesencephalic cisterns must be used to suggest the presence of brain stem injury.¹¹⁸ Isodense contusions not visualized on unenhanced CT scans will become evident with the use of intravenous contrast material.¹¹⁸ Brain stem injuries may be primary, occurring at the time of injury, or secondary, occurring at a later time from downward transtentorial herniation or direct compression by other lesions.¹¹⁸ Hemorrhagic lesions in the rostral midbrain may also occur at the time of injury (Fig. 9–33).⁸³ Injury to the brain stem carries a grave prognosis and is associated with a high mortality.¹¹⁹

MRI studies are equivalent to CT scans in the detection of hemorrhagic cortical contusions but are more sensitive in the detection of nonhemorrhagic contusions.^{39,136} In some cases, acute hemorrhagic contusions visible on CT scans may not be visualized with MRI.⁵⁰ As the hemorrhagic contusion evolves, it becomes isodense and finally hypodense on CT scans and is poorly seen. It is in the subacute and chronic stages that MRI studies are more sensitive than CT in the detection of contusions.⁵⁰ MRI studies also allow the contusions to be better characterized.⁶² Contusions tend to be multiple and to involve the cortex with sparing of the underlying white matter. A hemorrhagic component is evident in many lesions.³⁷

Acute hemorrhagic contusions are isointense or slightly hypointense in signal on T1-weighted images and very hypointense on T2-weighted images (Fig. 9–34). This feature reflects the preferential T2 shortening of intracellular deoxyhemoglobin. Subacute lesions are hyperintense on

Figure 9–32. Pontine contusion. Hemorrhagic contusion is seen in the left posterolateral pons (arrowhead).

Figure 9–33. Acute hemorrhagic contusion is demonstrated in the rostral midbrain (arrow). Note the effacement of the quadrigeminal cistern (arrowheads) and the left temporal lobe contusion (small arrow).

T1- and T2-weighted images because of the effect of extracellular methemoglobin (Fig. 9–35).⁴⁴ Hypointensity from hemosiderin and encephalomalacia are evident in chronic lesions. The discrepancy between CT and MRI in the detection of nonhemorrhagic contusions is due to the superior spatial resolution of MRI and its sensitivity in the detection of changes in water content in damaged tissue. The use of supplemental T2* GRE sequences should allow the detection of small hemorrhagic contusions that are visualized on CT scans but not with conventional SE MRI studies (Fig. 9–36).

In the posterior fossa, contusions typically occur along the posterolateral aspect of the midbrain and lateral aspect of the cerebral peduncle.³⁸ They are primary injuries occurring at the time of injury. Secondary injuries occur later in the ventral, ventrolateral, and paramedian aspects of the brain stem.³⁸ MRI studies are more sensitive than CT scans in the detection of contusions in the posterior fossa because of the lack of artifact from the adjacent bone. Indirect signs of brain stem injury, which may be the only abnormalities present on the CT scan, are well demonstrated in addition to intrinsic lesions.^{38,50} Secondary foci of hemorrhage, located in the midline of the rostral midbrain, occur from tearing of penetrating arteries that supply the brain stem.³⁸ Although a high percentage of patients with brain stem contusions and normal CT findings have a good clinical outcome, 20% with normal CT scans do poorly because of undetected lesions or secondary complications.⁷⁴ MRI stud-

Figure 9-34. A, Acute left temporal lobe hemorrhagic contusion is isointense with gray matter on sagittal T1-weighted (500/15) MR image (arrow). B, Hemorrhagic contusion is hypointense on axial T2-weighted (2500/80) image (arrow). Note additional hemorrhagic contusions in the right frontal and temporal lobes (arrowheads).

Figure 9-35. A and B, Subacute hemorrhagic contusion in left frontal lobe is hyperintense on coronal T1-weighted (500/15) and largely hyperintense on coronal T2-weighted (2500/80) MR images, indicating the presence of methemoglobin (arrows). In addition, there is a small left frontal, convexity subacute subdural hematoma (curved arrows).

Figure 9-36. A, Axial T2-weighted (2600/80) MR image shows no abnormality in a comatose patient. B, Axial T2* gradient-recalled echo (600/17), 20-degree flip-angle image reveals a small acute hemorrhagic contusion in the pons (arrow).

ies are more accurate in the assessment of subacute and chronic injuries and may provide a more reliable correlation with clinical findings to better predict clinical outcome.

Diffuse Axonal (Shear) Injury

Diffuse axonal (shear) injury is frequently encountered in patients with head trauma.³⁹ Shearing injuries to the white matter were first described in the CT literature in 1978¹²⁹ and have been described extensively in the neuropathological literature in the past. A study by Strich and Oxon¹¹⁵ in 1961 described these injuries as axonal tears with or without microscopically visible hematoma. They reported on five patients who sustained head injury, died of brain swelling, and were found at autopsy to have white matter degeneration. Midbrain damage in patients with closed head injury has been frequently described at autopsy. In another study, 80% of patients dying of injuries resulting from head trauma had midbrain lesions at autopsy that were not visualized by CT scans.⁹⁸ Although blunt head trauma has been associated with a significant number of hemorrhagic foci in the corpus callosum at autopsy,⁷² the outcome of corpus callosum hematoma is not invariably dismal, because many patients with such lesions diagnosed by CT scans have been shown to survive.

Coma, decerebrate posturing, vegetative state, and no increase in intracranial pressure are present in many patients with diffuse axonal injury.¹²⁹ This injury is caused by rotational forces that produce shear strain, resulting in tissue damage. Shear strain is maximum at the junction of tissues with different densities such as the gray-white junction.³⁷ The presence of diffuse axonal injury is of great prognostic significance because the lesions are often associated with a poor outcome.¹²⁹

CT findings in diffuse axonal injury include diffuse cerebral swelling, corpus callosal hemorrhage, and SAH. Hemorrhage may also be present in the area of the third ventricle and hemispheric white matter.¹³² Although CT scans do not reveal the actual axonal lesion demonstrated with histology, they do show the associated edema and hemorrhage (Fig. 9-37).¹²⁸

MRI studies are more sensitive than CT scans in the detection of diffuse axonal injury. Lesions are readily demonstrated by MRI in patients in whom the CT scan shows no abnormality.^{37-39,136} The injuries are demonstrated with CT only when greater than 1.5 cm or when present in the corona radiata or internal capsule.³⁹

Diffuse axonal injury lesions are usually multiple, range from 0.5 to 1.5 cm, and are typically oval or elliptical. The lesions are most commonly located in the subcortical white matter of the frontal and temporal lobes, splenium of the corpus callosum, corona radiata, and internal capsule (Figs. 9-38 and 9-39). The parieto-occipital lobes and cerebellum are less commonly involved.³⁷ In the brain stem, the lesions are located in the dorsolateral aspect of the midbrain and upper pons (Fig. 9-40). More than 80% of the lesions are nonhemorrhagic, being most evident as foci of hyperintensity on T2-weighted images.³⁸

Brain Swelling and Edema

Brain swelling and edema occur commonly in patients with head trauma. Brain swelling is observed more commonly in children than in adults.¹³¹ Minor episodes of trauma may result in brain swelling. Patients may experience a lucid interval after the episode of trauma, followed by the sudden onset of headache, nausea, vomiting, and

Figure 9-37. Diffuse axonal injury. CT scan demonstrates small hemorrhagic diffuse axonal injuries in the deep white matter and corpus callosum.

Figure 9-38. Diffuse axonal injury. Axial T2-weighted (2500/80) MR image demonstrates typical locations of diffuse axonal injury: subcortical white matter, corpus callosum, and corona radiata.

Figure 9-39. A and B, Diffuse axonal injury in two different patients. Hyperintense lesions are present in the splenium of the corpus callosum on axial T2-weighted (2500/80) MR images (arrows).

Figure 9-40. Axial T2-weighted (2500/80) MR image shows areas of diffuse axonal injury in the pons, middle cerebellar peduncles, and left-cerebellar hemisphere. The pontine lesion contains a focus of acute hemorrhage (*small arrow*). Hemorrhagic contusion is present in the left temporal lobe.

loss of consciousness.¹³¹ SAH and contusions are often seen in association with this type of abnormality.^{14, 55}

Brain swelling is evident in the majority of patients with head trauma, occurring at the time of injury or several hours afterwards.⁵⁵ CT findings consist of compression of the lateral and third ventricles and perimesencephalic cistern (Figs. 9-41 and 9-42). There is an associated increase in density of the white matter from transient hyperemia.¹³¹ It is thought that loss of autoregulation results in an increase in cerebral blood flow and blood volume. This increase in blood flow forces CSF out of the ventricles and subarachnoid space, resulting in the compressed appearance. Serial CT scans show the gradual resolution of brain swelling over a period of 3 to 5 days.⁵⁵ The initial white matter hyperdensity gradually returns to normal as the swelling subsides. In more than one third of cases in children, extracerebral collections and sulcal and ventricular enlargement are seen to develop on follow-up CT scans.¹³¹

Cerebral edema may be cytotoxic, interstitial, or vasogenic in origin. In the immediate post-traumatic interval, cerebral edema is vasogenic, reflecting breakdown of the blood-brain barrier with leakage of intravascular contents into and around areas of damaged tissue. Edema is evident as decreased density within and surrounding areas of contusion and intraparenchymal hematoma.^{26, 66, 82} Edema may occur as an isolated finding, appearing as an area of decreased density.⁶⁶ Cerebral edema typically appears 24 hours after injury, then increases and becomes maximum at 3 to 5 days and then gradually resolves.

Brain swelling and edema are evident with MRI stud-

Figure 9-41. Brain swelling. Effacement of the perimesencephalic cistern indicates brain swelling (*arrowheads*). Note the bilateral temporal lobe contusions.

Figure 9-42. Axial CT scan shows effacement of basal cisterns, and third ventricle representing brain swelling. Note pneumocephalus overlying the right frontotemporal convexity (*arrowheads*).

ies.^{37, 50, 62, 136} The exquisite sensitivity of MRI to the presence of extracellular free water enables the detection and visualization of small regions of edema, particularly on T2-weighted images.

Penetrating Injury

Gunshot wounds are a common cause of penetrating head injury. CT scans allow one to rapidly locate the position of a missile and determine the extent of intracranial injury.^{4, 109} The missile, its track and fragments, as well as skull fracture and displaced intraparenchymal bone fragments are readily identified (Fig. 9–43). Hematoma along the missile track, intraventricular hemorrhage and SAH, diffuse edema, and pneumocephalus, both extracerebral and intracerebral, are frequently seen on CT scans.¹⁰⁹ Laceration of a major blood vessel may result in massive intraparenchymal hemorrhage, which is an indication for early surgical intervention.¹⁰⁹ Injuries beyond the missile track may sometimes be seen if the missile is of a large-caliber or high-velocity type.⁴ Prognosis is best when damage is limited to a single lobe, worse with unilateral multilobe injury, and poorest with bilateral hemispheric injury.⁸⁸ Damage to vital structures such as the diencephalon and mesencephalon is also associated with a poor prognosis.¹⁰⁹ Complications of penetration injuries include CSF leak, osteomyelitis, abscess, and seizures.⁸⁸ Repeat CT scans may reveal the development of encephalomalacia along the missile track and intraparenchymal cystic areas

of CSF density.⁴ The presence of metal projectiles is a relative contraindication to an MRI study because projectiles containing steel are deflected when placed in a magnetic field. Nonferromagnetic missiles are a contraindication to MRI when they contain ferromagnetic contaminants.¹¹² Any metal distorts the local magnetic field, the magnitude of which depends on the degree of ferromagnetism of the metal alloy. In addition to undergoing deflection, stainless steel or alloys with ferromagnetic contaminants distort the local magnetic field to a greater degree than titanium compounds and, if in the region of interest, severely degrade image quality.

Vascular Injury

Injury to the carotid or vertebral arteries may be produced by blunt force, penetrating injury, strangulation, and hyperextension.⁴¹ Dissection, laceration, thrombosis, and pseudoaneurysm or arteriovenous fistula formation may occur.²⁰ The site of injury depends on the nature of the forces on the vessels and the occurrence of nearby skull fractures.⁸⁷ Arterial injury may be diagnosed with CT scanning; however, angiography remains the modality that best defines the site of arterial injury.

An intimal tear in the arterial wall may result in dissection and thrombus formation.⁸⁷ Although one third of patients are symptomatic at the time of injury, the majority experience a lucent interval varying from hours to days before the onset of symptoms.⁸⁷ Symptoms are variable and

Figure 9–43. A, Axial CT scans with bone window setting demonstrates missile adjacent to the left temporal bone, temporal bone fracture, and missile-fragments in brain parenchyma. B, Brain window setting reveals multiple hemorrhagic-foci in the frontal and temporal lobes, effacement of the basal cisterns, and pneumocephalus.

include headache, Horner's syndrome, transient ischemic attacks, and completed stroke.

The diagnosis of arterial dissection may also be accomplished with MRI studies.⁴² Abnormal signal intensity representing hemorrhage is seen in a thickened arterial wall on all pulse sequences. The signal intensity depends on the age of the hematoma. The hematoma is usually contained by a thin rim of hypointensity that represents the adventitia.

In addition, the arterial lumen appears narrow. Arteries normally appear hypointense or demonstrate flow void phenomena on MRI.⁹ In arterial dissection, the slow flow distal to the area of dissection produces hyperintense signal within the vessel lumen. However, the hyperintense signal is not specific for dissection and may be the result of slow flow from stenosis caused by atherosclerotic disease. The hyperintensity of slow arterial flow must be differentiated

Figure 9-44. A, Arterial dissection. Sagittal T1-weighted (500/15) MR image shows cortical ribbon of hyperintensity representing subacute hemorrhage in the right temporal lobe (arrowheads). B, Hyperintense signal is evident on axial T2-weighted (2500/80) image. Findings are consistent with acute infarction. C, Two-dimensional time-of-flight MR angiography study demonstrates irregular narrowing of the right vertebral artery consistent with dissection (arrows). D, Intraarterial digital subtraction angiogram of the right vertebral artery confirms the dissection (arrows).

Figure 9-45. A, Post-traumatic internal carotid artery aneurysm. Coronal T1-weighted (500/15) MR image shows aneurysm arising from left internal carotid artery (arrow). Note the small lumen of the internal carotid artery (arrowhead). B, Three-dimensional phase-contrast MR angiography study performed with a velocity encoding of 10 cm/second demonstrates flow within the aneurysm (arrow). C, Left common carotid arteriogram shows the aneurysm arising from the proximal cavernous internal carotid artery.

from arterial thrombosis, which appears as isointense signal within the vessel lumen. Arterial thrombus is composed of fibrin and platelets, rather than hemoglobin containing red blood cells, and as a result is isointense in signal intensity. This is in contradistinction to the signal intensity of intraparenchymal hematoma or venous thrombus in various stages of evolution.⁶⁷ Magnetic resonance angiography (MRA) can demonstrate the concentric luminal narrowing and irregularity of carotid dissection and may eliminate the need for conventional angiography (Fig. 9-44).

Disruption of the three layers of the arterial wall—intima, media, and adventitia—may result in pseudoaneurysm formation.⁸⁷ Symptoms are variable, include headache, tinnitus, and vertigo, and may appear years after injury.²⁰ Although CT and MRI studies are capable of demonstrating a pseudoaneurysm, angiography is required to accurately depict the lesion. The MRI appearance of a pseudoaneurysm is variable, depending on the size and presence of thrombus. Areas of signal void, representing

residual lumen, and areas of mixed signal intensity, representing thrombus of variable age, may be seen. An advantage of MRI is that it demonstrates the true size of the aneurysm, including the patent lumen as well as intraluminal thrombus, whereas conventional angiography demonstrates only the patent lumen (Fig. 9-45).

MRA has the capability to demonstrate both small and large aneurysms. Aneurysms as small as 3 mm may be visualized with current imaging techniques.^{1a} The three-dimensional time-of-flight technique is sensitive to the detection of small aneurysms, whereas the phase-contrast technique is better able to depict large aneurysms.^{53,99}

Laceration of the intracavernous carotid artery with rupture into the cavernous sinus results in traumatic carotid cavernous fistula.⁸⁹ Symptoms and signs include orbital bruit, proptosis, conjunctival redness and swelling, blurred vision, pain, and pulsatile exophthalmos. CT and MRI studies demonstrate proptosis, enlargement of the rectus muscles, superior orbital vein, and cavernous sinus

Figure 9-46. A, Carotid cavernous fistula. Axial T2-weighted image (TR = 2500 msec, TE = 80 msec). Increased flow void is present in the region of the cavernous right internal carotid artery (arrowheads). B, Coronal T1-weighted image (TR = 500 msec, TE = 15 msec) reveals dilatation of the right superior ophthalmic vein (arrowhead). C, Lateral projection of right internal carotid artery arteriogram demonstrates opacification of the right cavernous sinus (arrow) with drainage into the right superior ophthalmic vein (arrowheads).

(Fig. 9-46). MRI shows flow void within the enlarged superior ophthalmic vein and cavernous sinus. Angiography is, however, necessary to visualize the site of the fistula. Phase-contrast MRA studies show promise in the detection of the fistulous communication.¹²¹

Child Abuse

Child abuse is a major cause of morbidity and mortality. Most victims of child abuse are younger than 2 years, with the majority younger than 1 year; however, older children up to adolescence may also be victims.^{18,134} The abused child may present with a variety of symptoms, including

breathing difficulty, irritability, lethargy, poor feeding, and seizures.²⁷ The clinical outcome depends on the severity of the injuries sustained. Minor disabilities may be present, such as visual disturbance, extremity weakness, and seizures.¹⁸ Children with severe impairment, such as mental retardation, or those existing in a vegetative state require institutional placement. It is important to recognize the CT findings encountered in child abuse; these findings may be the only signs of abuse because commonly there is no external evidence of injury.¹³ Clinical features may not allow the differentiation of the abused child from the child injured in an accident.

The mechanism of injury in child abuse was previously thought to be caused by shaking—the so-called shaken

baby syndrome. Shaking alone, however, does not generate the force required to produce head injury.²⁶ Rather, most victims of child abuse have evidence of blunt trauma to the head, and it is the force of the blunt impact that is responsible for the observed head injuries.²⁷ The child is likely first shaken and subsequently thrown, and the head strikes an object—the so-called shaken impact syndrome.¹³

The most common CT finding seen in child abuse on early-generation CT scanners was an acute interhemispheric SDH located in the parieto-occipital area (Fig. 9–47). The SDH is secondary to tearing of the bridging cerebral veins at their attachment to the falx. Infarction or cerebral swelling in the parieto-occipital lobes was a frequent associated abnormality.^{133,134} The most common finding observed on later-generation CT scanners is SAH.¹⁸ Other findings frequently seen include cerebral edema, intraparenchymal hemorrhage, SDH, infarction, and skull fracture. It may sometimes be difficult to differentiate interhemispheric SDH from SAH, and in some instances, they may coexist.¹⁸ In children who are victims of strangulation, large infarctions and SDHs may be present, usually involving the supratentorial brain.¹⁶ Skull radiographs should be obtained in victims of child abuse because fractures may not be evident on CT scans. Radiographic features of skull fractures may allow the differentiation of the abused child from the child injured in an accident.⁸¹ These features are multiple, bilateral fractures that cross suture lines. Focal or diffuse atrophy with sulcal and ventricular enlargement is evident on repeat CT scans in all patients; infarction is evident in some patients.^{18,134}

Although CT scans are performed in acutely injured patients to exclude a surgical lesion, MRI studies should

be used when the clinical symptoms do not correlate with the CT findings. MRI is also more useful in the evaluation of subacute and chronic head injury because the technique is more sensitive than CT scans in the detection of small SDH, cortical contusion, and diffuse axonal injury. The advantage of MRI lies in the ability to determine the age of subdural blood on the basis of signal intensity. The presence of SDHs in various stages of evolution, signifying a difference in age, may be an indicator of child abuse.¹⁰⁰

Complications of Central Nervous System Trauma

Hydrocephalus

Hydrocephalus is a possible complication of head injury. Diffuse brain injury or obstruction of CSF pathways results in enlargement of the ventricular system. In the former, as diffuse edema resolves, there is a gradual enlargement of the ventricular system, which retains a normal configuration.²⁶ Noncommunicating hydrocephalus may be evident initially or shortly after injury, with intraventricular hemorrhage impeding the outflow of CSF at the level of obstruction.²⁶ Communicating hydrocephalus is the result of decreased absorption of CSF at the level of the arachnoid villi over the cerebral convexities. This may be observed as a gradual enlargement of the ventricular system on serial CT scan.⁶⁶ Enlargement of the ventricular system occurs in the majority of patients within 2 weeks of injury, however, it may rarely develop over several months to 1 year after injury.⁶⁵ The clinical outcome in patients who experience

Figure 9–47. A and B, Child abuse. Axial CT scans show an acute posterior interhemispheric subdural hemorrhage in the occipital area (arrows).

Figure 9-48. A, Hydrocephalus. Axial CT scan shows ventricular enlargement with massive intraventricular hemorrhage. A shunt tube is present in the right lateral ventricle. Posterior interhemispheric subdural hematoma and frontal lobe contusions are present. B, Ten days later, the intraventricular hemorrhage has resolved, and the ventricles have decreased in size but remain enlarged.

hydrocephalus is much worse than in those who do not, with the majority sustaining moderate to severe disability.⁶⁵

The CT appearance of communicating hydrocephalus consists of dilatation of the ventricular system and effacement of the cortical sulci (Fig. 9-48). In the acute stage, decreased density representing transependymal fluid shift is present in the periventricular white matter. The transependymal fluid shift is visible as a thin rim of hyperintensity in the periventricular white matter on proton-density and T2-weighted MR images. Other findings that may be observed are dilatation of the anterior third ventricle, inferior displacement of the hypothalamus, depression of the posterior fornix, and elevation of the corpus callosum—which are seen on sagittal T1-weighted images.²⁹

The CSF flow void sign is from the turbulent flow of CSF and indicates the presence of flow in the aqueduct of Sylvius and third and fourth ventricle.¹⁰⁶ Absence of the flow void sign in the aqueduct in the presence of hydrocephalus is an indication of obstruction or stenosis at the level of the aqueduct.¹⁰⁷ Intraventricular hemorrhage within the aqueduct results in absence of the flow void sign. The flow void sign is present in normal individuals as well as in patients with normal-pressure hydrocephalus, acute communicating hydrocephalus, and atrophy.¹¹ Although the flow void sign is present in all of these conditions, it is most evident in normal-pressure hydrocephalus and is not as evident in atrophy and acute communicating hydrocephalus.³¹ However, it cannot be used to differentiate acute communicating hydrocephalus from atrophy.¹⁰⁸

Atrophy

Areas of porencephaly may result from head trauma at the site of intracerebral hematoma or infarction. Porenceph-

aly is a cystic defect that may or may not communicate with the ventricular system. In the communicating type, the defect communicates with the ventricular system or is separated from it by only a thin layer of tissue. In closed porencephaly, the cyst does not communicate with the ventricular system. The CT appearance is that of a well-defined area of CSF density with no contrast enhancement.⁹⁴ Shift of the midline structures and the ventricular system is usually toward and rarely away from the defect. MRI studies demonstrate the porencephalic defect to be of CSF signal intensity on all pulse sequences.

Infarction

Infarction may be a sequela of head trauma secondary to vasospasm, vascular occlusion, or direct vessel damage.⁶⁶ In the acute stage, decreased density or isodense cerebral swelling with mass effect and midline shift may be seen on CT scans (Fig. 9-49).^{18,134} The use of intravenous contrast material demonstrates luxury perfusion around areas of infarction.¹⁸ Focal encephalomalacia or porencephaly with ventricular and sulcal dilatation are seen in the chronic stage.⁶⁶ MRI is more sensitive than CT in the detection of infarction. Brain swelling is seen on T1-weighted images within several hours after the onset of symptoms, before any signal change is evident on T2-weighted images.¹²⁷ Hyperintense signal may be evident between 8 and 24 hours on T2-weighted images, whereas the CT scan may be normal up to 2 days after the onset of symptoms. Intravascular and meningeal enhancement may be present within the first several days after administration of gadopentetate dimeglumine.^{30,127}

Figure 9-49. A, Infarction secondary to assault with a hammer. Unenhanced CT scan shows acute left frontal lobe infarction in the distribution of the left anterior cerebral artery. B, CT scan with bone window reveals nondepressed fracture of the left frontal bone (arrowhead).

Post-traumatic Leak

A CSF leak indicates abnormal communication between the intracranial and extracranial environments. It most commonly occurs after penetrating injury or fracture along the skull base and usually involves the cribriform plate or the temporal bone. CSF leak indicates communication with the paranasal sinuses and, less likely, the mastoid air cells or the middle ear cavity. The clinical significance ranges from entirely benign, because it is frequently self-limited, to infection and brain abscess if it is associated with persistent extracerebral communication.⁹⁷

The most common sites of fractures and CSF leaks are in the sphenoid region of the anterior cranial fossa. Leakage may occur through the nose, mouth, or the middle ear and depends on the location of the fracture. Precise detection of the sites of leakage is difficult. An air-fluid level in the sphenoid sinus suggests a fracture of the cribriform plate, although a CSF leak from anywhere between the frontal sinus and sphenoid bone may result in retrograde flow of CSF into the sphenoid ostium.¹¹⁶ Most CSF leaks are related to high-velocity trauma.^{68, 70, 97}

The demonstration of a post-traumatic leakage site requires thin-section, high-spatial resolution^{68, 70, 97} direct coronal scans. Such scans may demonstrate a bony dehiscence of the skull base near a sinus or an air cell and, thus, localize the level of air entry. A cisternogram may be of help if there is an active leak at the time of the study but is otherwise not necessary, particularly when high-spatial-resolution, direct coronal scanning is performed (Fig. 9-50).⁷⁷

Infection

Infection of the central nervous system may uncommonly occur as a complication of trauma associated with fracture. Direct extension of microorganisms through a

Figure 9-50. Post-traumatic cerebrospinal fluid leak. High-resolution direct coronal CT cisternogram demonstrates leakage of contrast material in the right ethmoid sinus (arrowhead) and the fracture site in the right cribriform plate (arrow).

Figure 9-51. A, Cerebritis. Axial T2-weighted image (TR = 2500 msec, TE = 80 msec) shows edema in the right frontal lobe. Small, bilateral, convexity subdural hematomas are present. B, Contrast-enhanced T1-weighted image (TR = 500 msec, TE = 15 msec) reveals focus of nodular enhancement (arrow).

Figure 9-52. Abscess secondary to right temporal bone fracture. Contrast-enhanced CT scan shows ring enhancing abscess caused by *Staphylococcus* in the right temporal lobe.

fracture site may result in meningitis, cerebritis, abscess, or, less commonly, subdural or epidural empyema. The initial CT scan is often normal with meningitis. A second CT scan may demonstrate hydrocephalus, effacement of the basal cisterns secondary to inflammatory exudate, and enhancement of the basal cisterns and meninges with intravenous contrast material.¹⁵ Contrast-enhanced MRI is more sensitive than contrast-enhanced CT in detecting meningeal enhancement.⁷⁸ Cerebritis is more readily demonstrated with MRI than with CT.^{47,101} Hyperintense edema is evident on T2-weighted images, whereas nodular enhancement can be seen on contrast-enhanced T1-weighted images (Fig. 9-51). Contrast-enhanced CT and MRI depict intraparenchymal abscess as a ring enhancing mass with surrounding edema (Fig. 9-52).

Tension Pneumocephalus

Air may enter the cranial cavity through a fistulous connection in sufficient amounts to cause mass effect.^{7,32,91} Its mechanism is poorly understood. This is a rare complication usually caused by trauma or surgery to the skull base, it has also been described after infection with gas-forming organisms or congenital defects of the skull base.⁷⁶

Neurodegenerative Disorders

Andrei I. Holodny, Ajax E. George,
Mony J. de Leon, Sassan Karimi

Advances in magnetic resonance imaging (MRI) have significantly improved the assessment of neurodegenerative disorders, including the dementias, hydrocephalus, and movement disorders. Often it is difficult to differentiate clinically between various neurodegenerative disorders and even between pathologic processes and the normal aging process. In recent years, specific and sensitive radiologic criteria have been developed to accurately establish the correct diagnosis in these disorders. MRI, with its ability to image the structure and function of the living brain, has become an invaluable tool. The value of understanding the MRI appearance of neurodegenerative disorders will increase as the population ages and as new therapies for these disorders are developed.

Normal Aging

The brain changes that occur as part of normal aging include ventricular and sulcal dilatation due to cerebral atrophy (Fig. 10-1).^{21, 26, 27, 46, 67, 75, 88, 102, 111} Despite these structural changes, cerebral metabolism, as measured by positron emission tomography (PET) with the glucose analogues fluorine deoxyglucose (18-FDG) and carbon deoxyglucose (¹¹C-2DG) does not decline with age.^{24, 25} The severity of normally occurring brain atrophy is variable, ranging from minimal to moderately severe. Sulcal dilatation is a prominent feature of the aging process, even in the absence of ventricular enlargement. Some subjects over 60 years of age show no ventricular enlargement and demonstrate only mild or no sulcal dilatation. These subjects may be more appropriately considered "supernormals" because of the minimal structural changes that are present despite their age.

On average, ventricular volume increases approximately twofold between young (ages 20 to 30) and elderly (ages 60 to 80) normal subjects. The ventricular volume remains relatively stable up to age 60 years, after which time there is an accelerated increase in size. MRI quantification studies of this type have confirmed the findings reported in the literature on computed tomography (CT) showing that in young normal subjects sulcal volume is approximately equal to that of the ventricular system. In normal subjects over age 60, sulcal volume is greater than that of ventricular volume.¹⁰² MRI-based measurements have shown that in normal healthy volunteers the volumes of the hippocampus, amygdala, and temporal horn remain stable until age 60, with progressive volume loss seen with more advanced age.⁸⁶

Dementia

Dementia can be caused by myriad pathologic processes: (1) *anatomic* (e.g., tumor, subdural hematoma, or normal-pressure hydrocephalus), (2) *physiologic* (electrolyte imbalance), or (3) *psychiatric* (depression). It is often difficult to establish the cause by clinical examination alone. During radiologic assessment, it is imperative to rule out the presence of treatable causes of dementia. The advent of new pharmacologic agents and neurosurgical techniques has increased the number of dementias, which are at least potentially treatable, making the accurate radiologic assessment even more important.

Alzheimer's Disease

Alzheimer's disease (AD)^{6, 7} has been recognized as one of the most significant health problems of the 20th century.⁷³ AD is estimated to afflict 10% of people over 65 years of age and 50% of individuals over age 85 years.³⁷ It is the most common dementing disorder of the elderly.¹¹⁹ According to the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*²⁹ patients with AD present with "a multifaceted loss of intellectual abilities, such as memory, judgment, abstract thought, and other higher cortical functions, and changes in personality and behavior." However, these clinical findings are not specific for AD and often are seen with other causes of dementia.

In up to 40% of cases, genetic factors have been implicated in the etiology of AD. Three genes, when mutated, have been identified to cause AD. Some cases of AD are inherited as autosomal dominant trait. In addition, sporadic cases have been identified and account for up to 20% of cases of AD.²²

A number of pharmacologic trials have been undertaken to improve or stem the advancement of the clinical symptoms of AD. Some have been encouraging. Cholinergic enhancement achieved by pharmacotherapy improves cognitive and noncognitive abilities in a number of patients.⁴²

With the introduction of CT in the 1970s, investigators tried to correlate the degree of cerebral atrophy to the degree of dementia in patients with AD. Several early CT studies reported ventricular and sulcal enlargement in association with AD.^{21, 26, 27, 46, 75, 79, 80, 111, 114} These atrophic changes, therefore, accentuate those of normal aging. However, there was a large overlap between patients with AD and normal age-matched controls. Some patients with severe cortical atrophy had normal cognition, whereas some patients with severe dementia had minimal cortical atrophy.

Figure 10-1. A, T2-weighted transverse axial image at the level of the bodies of the lateral ventricles in a normal, elderly male volunteer. B, Negative angle (infraorbital-meatal plane) cut at the level of the temporal horns. C, Coronal T1-weighted gradient-echo image at the level of the hippocampus. There is mild cortical atrophy. The lateral ventricles are not appreciably enlarged. The temporal lobes show minimal, if any, atrophy. Prominent perivascular (Virchow-Robin) spaces emanate from the lateral ventricles (A), representing a normal variant. Faint peritrigonal T2 hyperintensities in A indicate minimal microvascular disease.

Neuropathologic evidence has shown severe focal cell loss and neurofibrillary tangle formation of the subiculum and entorhinal cortex in AD.⁸⁸ The focal pattern of pathology in this region apparently isolates the hippocampal formation from much of its output and input, thereby contributing to the memory disorder characteristic of AD patients. The pathologic changes include senile plaques, neurofibrillary tangles, and granulovacuolar degeneration with progressive neuronal loss and atrophy of the hippocampal formation.^{10, 64, 74, 121} There are also neural transmitter deficits and a severe loss in the density of synaptic terminals.⁵⁷ In view of the involvement of this region, AD has been characterized as a hippocampal dementia.¹⁰

In view of this neuropathologic evidence, imaging studies, including our own,^{21, 26, 27, 46, 75, 76, 79, 80, 111, 114} have focused on specific evaluation of the temporal lobes. These studies strongly suggest that AD may be diagnosed in life by MRI or CT. Thus, the role of neuroimaging and the diagnosis of this process, which has long been based on the method of exclusion, is now changing.

The transverse fissure of Bichat separates the telencephalon from the diencephalon. A medial part separates the thalamus from the fornix and corpus callosum, and a lateral part is situated between the thalamus and the parahippocampal gyrus. Medially the transverse fissure communicates with the perimesencephalic cistern⁶⁰ (Figs. 10-2 and 10-3).

Figure 10-2. Normal anatomy of the brain Coronal pathologic section through the medial temporal lobe, including the hippocampus (H). The perihippocampal fissures, including the transverse fissure of Bichat (large arrow), the hippocampal fissure (small arrows), and the choroidal fissure (curved arrows) are seen. The transverse fissure of Bichat communicates with the perimesencephalic cistern (lower left). The choroid plexus and the fimbria (arrow with square) form a physical barrier between the temporal horn (TH) and the choroidal fissure. PH, parahippocampal gyrus. (From Holodny AI, George AE, Golomb J, et al: The perihippocampal fissures: Normal anatomy and disease states. Radiographics 18:653-665, 1998.)

Figure 10-3. Normal brain anatomy. Coronal diagram shows the medial temporal lobe structures, including the perihippocampal fissures. The medial aspect is to the left and the lateral aspect is to the right. The perihippocampal fissures are visible but are not dilated. The choroid plexus (Ch) and the fimbria (F) form a physical barrier between the temporal horn (TH) and the choroidal fissure (CF). CN, caudate nucleus; H, hippocampus; HF, hippocampal fissure; PMC, perimesencephalic cistern; S, subiculum; TFB, transverse fissure of Bichat. (From Holodny AI, George AE, Golomb J, et al: The perihippocampal fissures: Normal anatomy and disease states. Radiographics 18:653-665, 1998.)

Figure 10-4. Anatomic changes in a patient with Alzheimer's disease. Coronal diagram shows the medial temporal lobe structures, including the perihippocampal fissures. Compared to the normal individual in Figure 10-3, there is volume loss of the hippocampus and corresponding dilatation of the perihippocampal fissures. The choroid plexus (Ch) and the fimbria (F) form a physical barrier between the temporal horn (TH) and the choroidal fissure (CF). CN, caudate nucleus; H, hippocampus; HF, hippocampal fissure; PMC, perimesencephalic cistern; S, subiculum; TFB, transverse fissure of Bichat. (From Holodny AI, George AE, Golomb J, et al: The perihippocampal fissures: Normal anatomy and disease states. Radiographics 18:653-665, 1998.)

Temporal lobe changes are highly sensitive markers of AD.^{27, 46, 61} The use of either CT or MRI negative-angle thin-section cuts that parallel the temporal lobes or coronal thin-section MRI scans perpendicular to the axial plane maximizes the demonstration of temporal lobe pathology. Almost all patients with AD show at least a moderate degree of hippocampal atrophy as well as atrophy of the parahippocampal gyrus, dentate gyrus, and subiculum. These atrophic changes lead to enlargement of the transverse fissure of Bichat and the hippocampal and choroidal extensions as well as dilatation of the temporal horn (Fig. 10-4). Although high-resolution coronal images display this anatomy optimally, even mild hippocampal atrophy and the resultant dilatation of the perihippocampal fissures can be seen on standard MRI and CT images²⁷ (see Figs. 10-5 and 10-6).

The longitudinal study of normal subjects and patients with AD for structural brain changes shows a greatly increased rate of change in the AD patients as compared with normal subjects.^{26, 41} We found that 90% of patients with AD showed progressive atrophy of the temporal lobes when they were longitudinally studied over a 3-year period²⁶ (see Fig. 10-12). More important is that the presence of medial temporal lobe atrophy in **normal individuals**⁴⁹ may represent a significant risk factor for the subsequent development of AD.²⁷

In addition, it appears that an atrophic hippocampus not only is a radiologic marker for the presence of AD but also may actually serve as a predictor for the future development of this disorder. In a landmark study by de Leon and coworkers,²⁷ 86 older adult patients who were either normal

Figure 10-5. Clinical Alzheimer's disease. Reverse-angle CT scan (angled parallel to the hippocampus) demonstrates an area of decreased density in the medial aspect of the temporal lobe (arrow). The density of this area approaches that of cerebrospinal fluid. This corresponds to dilatation of the perihippocampal fissures and is an accurate indicator of hippocampal atrophy. (From Holodny AI, George AE, Golomb J, et al: The perihippocampal fissures: Normal anatomy and disease states. Radiographics 18: 653-665, 1998.)

Figure 10-6. Presumed Alzheimer's disease in a 60-year-old woman. *A*, Coronal T1-weighted MR image demonstrates severe atrophy of the hippocampus and dilatation of the perihippocampal fissures. *B* and *C*, Reverse-angle axial T2-weighted images in the same patient. These images demonstrate the importance of evaluating for prominence of the perihippocampal fissures and hippocampal atrophy in the correct plane. *B* is inferior to *C*. In *B*, the left medial temporal lobe demonstrates prominent perihippocampal fissures (the area of increased signal intensity between the temporal horn and the pons). The right medial temporal lobe on image *B* fails to demonstrate this area of increased signal intensity. This is because the patient is slightly tilted and one is actually scanning through the area of the parahippocampal gyrus (see Fig. 10-1), not the atrophic hippocampus. An analogous situation exists in *C*. The dilated perihippocampal fissures are seen on the right. The scanning plane on the left side is directed superior to the perihippocampal fissures and therefore does not demonstrate the area of increased signal intensity associated with dilated perihippocampal fissures. (From Holodny AI, George AE, Golomb J, et al: The perihippocampal fissures: Normal anatomy and disease states. Radiographics 18: 653-665, 1998.)

or who had minimal cognitive impairment were monitored for four years. Dilatation of the perihippocampal fissures at the time of entry into the study was a predictor of future deterioration and development of AD, with a sensitivity of 91% and a specificity of 89%.

Hydrocephalus

Classification

Hydrocephalus, from the Greek *hydro* (water) and *cephalus* (brain) is an abnormal accumulation of intracranial fluid (i.e., water on the brain) resulting from a structural or functional block to the normal flow of cerebrospinal fluid (CSF). The ventricles may become significantly enlarged.

The diagnosis of hydrocephalus in patients under age 60 years is usually straightforward. In patients over age 60, however, often confounding superimposed changes of atrophy are caused by normal aging and possible coexisting AD.⁴⁸ Hydrocephalus is initially associated with increased intracranial pressure, but it may later reach a state of equilibrium known as *arrested*, or *normal-pressure, hydrocephalus*.

When the block to the flow of CSF occurs along the ventricular system, the condition is known as *obstructive hydrocephalus*. Since all hydrocephalus is obstructive, the term *intraventricular obstructive hydrocephalus* has been proposed as a more accurate description for this type of obstruction. If the block to CSF is distal to the ventricular system, either at the base of the skull or as distal as the level of the pacchionian granulations, the hydrocephalus is described as *communicating* (i.e., the ventricular system communicates with the extraventricular subarachnoid space). A more accurate term for this condition would therefore be *extraventricular obstructive hydrocephalus*. The term *hydrocephalus ex vacuo* is sometimes used to refer to cerebral atrophy; this term is best avoided, however, because of its confusing implications.

The terms *communicating hydrocephalus* and *noncommunicating* (or *obstructive*) *hydrocephalus* have prevailed since the early days of neuroradiologic diagnosis. Dandy and Blackfan²³ introduced a color dye (phenolsulfonphthalein) by ventricular catheter into the hydrocephalic ventricular system. If the color dye could be extracted by lumbar

spinal tap within 2 to 3 minutes, the hydrocephalus was then described as “communicating.” If the dye did not appear on spinal tap or was greatly delayed, the hydrocephalus was considered obstructive, or “noncommunicating.”

The CT and MRI features of communicating hydrocephalus are as follows:

1. *Early dilatation and rounding of the temporal horns.* These features may be the earliest manifestation of ventricular obstruction and may be seen before obvious enlargement of the bodies of the lateral ventricles. In contradistinction, temporal horn dilatation as a manifestation of temporal lobe atrophy occurs later in the progression of a degenerative brain disease and is invariably associated with the presence of enlargement of the perihippocampal fissures (the transverse fissure of Bichat, and the choroidal and hippocampal fissures). The cisternal spaces and their extensions (the perihippocampal fissures) do not communicate with the temporal lobe; therefore, the dilatation of the temporal horn caused by obstructive hydrocephalus may actually displace the hippocampus medially and cause compression of the perihippocampal fissures⁵⁹ (Figs. 10–7 and 10–8).
2. *Rounding and enlargement of the frontal horns.* Figure 10–8 shows the MRI scan of a 47-year-old woman with hydrocephalus. The scan shows severe lateral and third ventricular dilatation. The frontal horns are ballooned, and the angle formed by their medial walls (the septal angle) is acute. In atrophy, the frontal horns are typically enlarged but not ballooned. The septal angle is often obtuse.
3. *Enlargement and ballooning of the third ventricle.* In atrophy, the third ventricle tends to enlarge by increasing the distance between its walls, which tend to remain parallel to each other. Ballooning and rounding of the third ventricle are characteristic of hydrocephalus. In the sagittal projection, the roof of the third ventricle may be flattened by the often huge lateral ventricular bodies.
4. *Severe dilatation of the bodies of the lateral ventricles and increased height of the ventricles.* The degree of dilatation of the lateral ventricles in hydrocephalus is typically notably greater than that occurring secondary to atrophy. The corpus callosum is thinned and bowed, forming an arch. Interpeduncular height may be decreased.³⁵ Typically, a patient with severe ventricular

Figure 10–7. Anatomic changes in hydrocephalus. Coronal diagram shows the structures of the medial temporal lobe, including the perihippocampal fissures. Compared to the normal individual in Figure 10–3, there is dilation of the temporal horn of the lateral ventricle. The hippocampus is displaced medially, and the perihippocampal fissures are compressed. The choroid plexus (Ch) and the fimbria (F) form a physical barrier between the temporal horn (TH) and the choroidal fissure (CF). CN, caudate nucleus; H, hippocampus; HF, hippocampal fissure; PMC, perimesencephalic cistern; S, subiculum; TFB, transverse fissure of Bichat. (From Holodny AI, George AE, Golomb J, de Leon MJ, Kalnin AJ: The perihippocampal fissures: Normal anatomy and disease states. Radiographics 18:653–665, 1998.)

Figure 10-8. Hydrocephalus in a 47-year-old patient. *A*, Sagittal T1-weighted image demonstrates dilatation of the lateral, third, and fourth ventricles. There is bowing of the corpus callosum. *B*, Axial fluid-attenuated inversion recovery (FLAIR) image demonstrates marked dilatation of the ventricles out of proportion to the sulci. *C* and *D*, Coronal T1-weighted images demonstrate marked dilatation of the lateral ventricles, including the temporal horns. There is no hippocampal atrophy. *E*, Hydrocephalus is confirmed on this axial T2-weighted image. (From Holodny AI, George AE, Golomb J: Neurodegenerative disorders. In Edelman R, Hesselink JR (eds): Clinical Magnetic Resonance Imaging, 2nd ed. Philadelphia, WB Saunders, 1996.)

dilatation caused by hydrocephalus may show a minimal cognitive deficit. In contrast, a patient with comparably severe ventricular dilatation caused by atrophy usually shows profound cognitive impairment. Note the relatively modest ventricular enlargement in patients with severe dementia. A motoric deficit, especially gait impairment, is a characteristic feature of hydrocephalus. The motoric deficit may be severe to the point that patients may be wheelchair-bound or bed-bound. Ventricular shunting in these patients may have dramatic results, with significant improvement in gait and motor function.

5. *Enlargement of the fourth ventricle.* This finding presupposes that the hydrocephalus is communicating. In chronic obstructive hydrocephalus, however, the fourth ventricle may also enlarge secondarily from incisural obstruction created by the enlarged ventricles, dilated temporal horns, and swollen temporal lobes, which tend to herniate into the incisural notch. When present, dilatation of the fourth ventricle can be helpful in establishing the diagnosis of hydrocephalus. However, fourth-ventricular enlargement may be absent or minimal despite the presence of definite hydrocephalus.
6. *Sulcal effacement.* When present, sulcal effacement is usually diagnostic of hydrocephalus in the elderly age group because cortical atrophy is almost invariably present as part of the normal aging process. Hydrocephalus, however, may coexist with large sulci and, in particular, with large sylvian fissures. This occurs when the block is at the level of the high convexity or the pacchionian granulations. Consequently, the sulci and fissures dilate because of the damming of fluid proximal to the block. In effect, the sulci and fissures dilate in the same way as the ventricular system because of the distal obstruction. In such patients, ventricular shunting may lead to collapse of the sylvian fissures, the sulci, and other convexity CSF collections.⁶⁰
7. *Periventricular edema.* This finding is seen especially in the periventricular white matter of the frontal horns in acute and subacute phases of hydrocephalus. In older people, however, it is usually not possible to distinguish between periventricular T2 changes resulting from microvascular parenchymal disease (see later) and the periventricular edema of hydrocephalus. In fact, hydrocephalus may lead to chronic microvascular changes, as shown in animal hydrocephalus models.⁵⁹ It was initially thought that MRI might help identify ventricular enlargement due to hydrocephalus by the presence of a periventricular high-signal halo on T2-weighted images. Because periventricular high-signal changes as a result of microvascular disease are also seen, the finding is therefore nonspecific and not helpful.⁹⁷ Furthermore, in chronic stages of hydrocephalus, periventricular edema resolves and is not visualized by either CT or MRI.

Obstructive Hydrocephalus

The sites where the ventricular system is normally narrow (i.e., the foramina) are particularly vulnerable to obstruction. Causes of intraventricular obstruction at the level of the foramen of Monro include (1) colloid cyst of the

third ventricle, (2) ependymoma, (3) teratoma, (4) congenital atresia, and (5) involvement by adjacent glioma.

The posterior third ventricle may be obstructed by pinealomas and aneurysms of the vein of Galen. Aqueductal obstruction can also occur in association with aqueductal stenosis, periaqueductal gliomas, arteriovenous malformations, and cysts of the quadrigeminal region.

Communicating Hydrocephalus

Communicating hydrocephalus may result from previous infection such as meningitis or may be secondary to previous hemorrhage caused by trauma, surgery, or rupture of an aneurysm with subarachnoid hemorrhage. It is also seen in association with Arnold-Chiari malformation and in the presence of subarachnoid seeding of tumor (meningiomas). A functional hydrocephalus in the presence of elevated CSF protein is seen in association with spinal cord tumors, typically ependymomas. Overproduction of CSF caused by choroid plexus papilloma or carcinoma may also result in hydrocephalus.

Normal-Pressure Hydrocephalus

An idiopathic form of communicating hydrocephalus, usually seen in older adults and known as normal-pressure hydrocephalus (NPH), was described originally by Adams and Hakim and their colleagues.^{3, 56} These authors reported a clinical triad of gait impairment characterized as magnetic gait, dementia, and urinary incontinence. Symptoms can be relieved by ventricular shunting, with the most dramatic improvement usually seen in gait. The typical patient with NPH who is likely to respond to a shunt exhibits a mild cognitive impairment along with a significant gait disturbance.

Differentiating NPH from cerebral atrophy can be extremely difficult. Initial enthusiasm for the concept of NPH as a treatable cause of dementia and gait impairment resulted in shunt procedures in patients who either failed to respond or showed an initial improvement but subsequently continued to deteriorate. Because of these discouraging results, the number of shunt procedures for NPH in the elderly has significantly decreased. The failure of patients to respond to the shunt procedure probably resulted from erroneous diagnosis of hydrocephalus in patients who were suffering from degenerative brain disease such as cerebral atrophy associated with AD. This has led to more stringent criteria to identify potential shunt candidates. These criteria include (1) radioisotope cisternography,⁸⁴ (2) continuous intracranial pressure recordings,⁹⁸ (3) spinal effusion,⁹⁰ and (4) CT cisternography with intrathecal iodinated contrast material.³⁶ Despite these criteria, a reliable study predicting shunt outcome has not been established.

In terms of MRI, two approaches can be used to differentiate NPH from cerebral atrophy: the anatomic approach and the functional approach. Anatomically, in patients with AD, volume loss of the hippocampus develops and resultant dilatation of the perihippocampal fissures ensues (see Fig. 10-4). Patients with NPH have dilatation of the temporal horn (Fig. 10-7).⁶¹ Although the hippocampus and the

Figure 10-9. Clinical Alzheimer's disease in a woman. Reverse-angle axial T1-weighted MR image (Global Deterioration Scale = 5). There is decreased signal intensity between the temporal horns and the perimesencephalic cistern. This represents dilatation of the perihippocampal fissures (PHFs) and atrophy of the structures of the medial temporal lobe, including the hippocampus. The size of the PHFs was assessed as moderately dilated. Compare with Figures 10-11 and 10-12. (From Holodny AI, Waxman R, George AE, et al: MR differential diagnosis of normal-pressure hydrocephalus and Alzheimer disease: Significance of the perihippocampal fissures. *AJNR Am J Neuroradiol* 19:813-819, 1998.)

Figure 10-10. Alzheimer's disease in a 73-year-old patient. Axial T2-weighted images angled parallel to the hippocampi demonstrate marked atrophy of the hippocampus and marked dilatation of the perihippocampal fissures. By comparison, the ventricles and cortical sulci are only mildly dilated. Compare with Figures 10-11 and 10-12. (From Holodny AI, Waxman R, George AE, et al: MR differential diagnosis of normal-pressure hydrocephalus and Alzheimer disease: Significance of the perihippocampal fissures. *AJNR Am J Neuroradiol* 19:813-819, 1998.)

Figure 10-11. Reverse-angle axial T1-weighted MR image of normal-pressure hydrocephalus in a 72-year-old man who improved after the placement of a ventriculoperitoneal shunt. There is no abnormally decreased signal intensity of the structures of the medial temporal lobes; therefore, there is no dilatation of the perihippocampal fissures or atrophy of the structures of the medial temporal lobe, including the hippocampus. The size of the perihippocampal fissures was graded as normal. This is in contrast to the patients from the group with Alzheimer's disease in Figures 10-9 and 10-10. There is dilatation of the temporal horns to a degree similar to patients from the Alzheimer group. (From Holodny AI, Waxman R, George AE, et al: MR differential diagnosis of normal-pressure hydrocephalus and Alzheimer disease: Significance of the perihippocampal fissures. *AJNR Am J Neuroradiol* 19:813-819, 1998.)

perihippocampal fissures are best seen in the coronal plane on MRI, it is important to stress that the anatomic changes occurring in NPH and AD can be appreciated to a large degree on axial MRI and CT (Figs. 10-9 to 10-12).⁵⁹

Occasionally, patients with NPH present with dilated sylvian fissures and rarely with focally dilated cortical sulci.⁶⁰ In a number of cases of shunt-proven NPH, there was actually paradoxical decrease in the size of the dilated cortical fissures and sulci that paralleled the decrease in the size of the lateral ventricles following successful shunting. Therefore, sulcal dilatation (especially when focal) should not be taken to imply cortical atrophy, and the maxim that hydrocephalus is defined as ventricles dilated out of proportion to the sulci does not always apply (Figs. 10-13 and 10-14).

Because AD is rather prevalent in the elderly, it can occasionally coexist with NPH. Earlier literature suggested that patients with dementia due to AD are not candidates for intraventricular shunting. However, more recent work suggests that for patients with accurately diagnosed NPH, concomitant AD does not strongly influence the clinical response to shunt placement.⁵⁰

Another MRI approach to the diagnosis of NPH is the quantification of CSF flow in the aqueduct. Work by Bradley and coworkers¹⁴ has demonstrated that in patients with shunt-proven NPH, the CSF stroke volume and CSF velocity in the aqueduct are both increased. However, the presence or absence of a flow void in the aqueduct does not appear to be an accurate predictor of shunt response.¹⁴

Figure 10-12. Reverse-angle axial T1-weighted MR image of a patient with normal-pressure hydrocephalus. There is a mild degree of decreased signal intensity of the structures of the medial temporal lobes. Therefore, the size of the perihippocampal fissures was graded as mildly dilated. Compare with Figures 10-9 and 10-10. (From Holodny AI, Waxman R, George AE, et al: MR differential diagnosis of normal-pressure hydrocephalus and Alzheimer disease: Significance of the perihippocampal fissures. *AJNR Am J Neuroradiol* 19:813-819, 1998.)

In summary, using the combination of radiologic and clinical criteria in conjunction with the results of measurements of cerebral blood flow and cerebral metabolism, we may more reliably and with greater accuracy identify patients with hydrocephalus who are likely to respond to shunt. Functional MRI techniques now becoming available may noninvasively provide similar functional information as that derived from PET and single photon emission computed tomography (SPECT). As a result of these advances, interest has been renewed in the surgical management of patients with hydrocephalus.

Pick's Disease

Pick's disease, another cause of dementia in adults, was first described in 1892.⁹⁷ The onset of dementia is often in the presenile age group, and a familial occurrence has been reported.⁵⁴ Pick's disease is much less prevalent than AD. The clinical presentation in most patients is suggestive of frontal lobe damage. There is an insidious deterioration in intellectual capacity and difficulty in concentration and memory. There is a slow but steady progression to marked dementia, which is usually more rapidly progressive than with AD.

On pathologic examination, there is atrophy of the brain, particularly of the frontal lobes and the anterior aspects of the temporal lobes. The parietal and occipital lobes are usually spared. Histologically, there is an intense loss and misalignment of neurons as well as subcortical gliosis in the affected areas of the brain. Many of the remaining neurons are small and contain characteristic intracytoplasmic, argentophilic inclusion bodies (Pick's bodies), which are well seen with Bielschowsky silver stain and antibody immunostaining.²

Prior to the advent of cross-sectional imaging, Pick's disease could be definitively diagnosed only at autopsy; however, the introduction of CT and MRI has allowed for the accurate diagnosis of Pick's disease in vivo and to differentiate it from other neurodegenerative disorders.⁴⁰ Radiographically, Pick's disease parallels the findings seen on pathologic studies, and marked atrophy of the anterior temporal and frontal lobes are characteristics. The sulci of these lobes become so atrophic that they have been described as icicle-like. There is usually a sparing of the posterior aspect of the superior frontal gyrus and the brain posterior to it.³³

Leukoencephalopathy of Aging, Multi-Infarct Dementia, and Binswanger's Disease

MRI is exquisitely sensitive to the detection of white matter disease. As in the atrophic changes described in the first part of this chapter, understanding the MRI characteristics and the underlying pathophysiology can allow one to arrive at the accurate diagnosis. Since this chapter focuses on neurodegenerative diseases, it covers only the limited number of white matter diseases that apply to this category.

Long repetition time (TR) (T2, proton-density) and fluid-attenuating inversion recovery [FLAIR] hyperintensities are common in the elderly.⁴⁵ These white matter lesions

Figure 10-13. Shunt-proven normal-pressure hydrocephalus in a patient with prominent focal sulcal dilatation. Axial CT scans through the bodies of the lateral ventricles (A) and third ventricle (B) and midsagittal MR image (C) demonstrate marked dilatation of the lateral ventricles. The temporal horns are moderately enlarged. The third ventricle is severely dilated and rounded. There is marked dilatation of the following sulci: the sylvian fissures bilaterally, the central sulci bilaterally, the anterior aspect of the interhemispheric fissure, the left parieto-occipital fissure and the left calcarine fissure. In addition, there is marked focal dilatation of the cingulate sulcus on the right, the precentral sulcus on the left, and the frontal sulci bilaterally. There is also dilatation of the suprasellar and quadrigeminal plate cisterns. The remaining sulci are compressed. There is no evidence of dilatation of the choroidal and parahippocampal fissures, hippocampal atrophy, or cerebellar or brain stem abnormalities. (From Holodny AI, George AE, de Leon MJ, et al: Focal dilatation and paradoxical collapse of cortical fissures and sulci in patients with normal-pressure hydrocephalus. *J Neurosurg* 89:742-747, 1998.)

are typically patchy or punctate and involve the peritrigonal region preferentially. The second most common area involves the white matter adjacent to the frontal horns. Brain stem lesions are less common. Typically, this process spares the arcuate fibers and the corpus callosum. Various terms have been used to describe this process, including *leukoencephalopathy*, *leukoaraiosis*,^{16,55} *deep white matter ischemia*, or *white matter hyperintensities of aging*,

the lesions are strongly related to age and have increasing prevalence in individuals over age 60 years.⁴⁴ It is also seen earlier and to a greater degree in patients with microvascular diseases, such as diabetes and hypertension. White matter is more susceptible than gray matter to chronic ischemic changes because it is supplied by long, small-caliber vessels, which are affected by these diseases.

Figure 10-14. Normal-pressure hydrocephalus in a 68-year-old man with paradoxical collapse of the sylvian fissures. *A* and *B*, Axial T1-weighted images demonstrate enlarged lateral ventricles, including the temporal horns as well as moderately distended sylvian fissures. Several months after successful shunting, the patient returned with recurrent symptoms. *C*, A CT scan demonstrated evidence of shunt failure with distention of the lateral ventricles. Sylvian fissure dilatation was also present. *D*, Following shunt revision, a CT scan demonstrated a decrease in the size of the lateral ventricles as well as a decrease in the size of the sylvian fissures. (From Holodny AI, George AE, de Leon MJ, et al: Focal dilatation and paradoxical collapse of cortical fissures and sulci in patients with normal-pressure hydrocephalus. *J Neurosurg* 89:742-747, 1998.)

Leukoencephalopathy cannot be considered a benign entity.¹⁶ We and others have found that these brain changes are related to gait disturbances and increased incidence of falls in the elderly,⁸³ deficits of fine motor coordination,⁷⁷ and an increased frequency in cerebral infarcts.^{44, 45, 69, 122} The increased incidence of falls is particularly of concern in older people.⁸³ The microvascular lesions themselves are not associated with dementia; however, the cognitive deficit associated with preexisting AD or other dementing disorders may be potentiated by the presence of the white matter lesion.⁴⁴

Autopsy work, including our own, has shown changes of the hypertensive type in the white matter associated with hyalinosis of arterioles and rarefaction of the white matter.^{19, 44, 52, 82, 100} In addition, mild gliosis, increased interstitial fluid, and "myelin pallor" are seen. Frank infarction occurs in more advanced cases and can be seen as well-defined areas of decreased signal intensity on the T1-weighted images. The T1 characteristics allows one to differentiate leukoencephalopathy from frank infarction.

Multiple-infarct dementia (MID) is the second most common cause of dementia in the elderly representing 10% to 20% of cases in patients over 65 years old.¹²¹ Clinically, these patients present with a sudden onset of dementia, day-to-day fluctuation, and spontaneous improvement early in the disease. These patients present radiographically with focally dilated fissures and multiple areas of focal cortical volume loss. Multiple subcortical infarcts and infarcts involving certain strategic structures (e.g., parts of the thalamus, caudate, or genu of the internal capsule) can also result in dementia.⁸¹

In 1894, Binswanger⁶ described a slowly progressive disease characterized by loss of memory and intellectual impairment associated with recurring neurologic deficits. Binswanger was apparently describing a type of multi-infarct dementia with severe hypertensive type microvascular changes, multiple subcortical infarcts, and dementia. The presence of periventricular T2 hyperintensities on MRI scans should not prompt a diagnosis of *Binswanger's disease* or multi-infarct dementia unless evidence clearly shows that infarcts are also present and that dementia is clinically present. Multiple infarcts, whether cortical or subcortical and especially when bilateral, may be associated with dementia. One should also keep in mind that even numerous subcortical infarcts may lead to only mild dementia. Because periventricular white matter hyperintensities are widely prevalent, especially in the elderly, the terms *multi-infarct dementia* and *Binswanger's disease* should not be used to describe these radiologic findings.⁹⁵

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is a rare cause of rapidly progressive dementia and is one of several associated neurodegenerative illnesses whose pathogenesis is related to a small, nonviral, 30- to 35-kD proteinaceous infectious particle known as a *prion*. The loci of pathology involve the cerebral and cerebellar cortices as well as the basal ganglia, where neuronal loss, reactive astrocytosis and the formation of cytoplasmic vacuoles within the glia and neurons give the tissue a characteristic spongiform appear-

ance on light microscopy. All of these changes occur in the absence of an inflammatory response.

The clinical syndrome is typically one of rapid cognitive decline, often with psychosis and delirium. Motor abnormalities of cerebellar dysfunction can appear, and almost all patients evidence pronounced myoclonus prior to the final phase of deepening unresponsiveness and coma. The time course of the disease from presentation until death is usually less than 1 year.

In the very early stages of the disease, CT and even MRI findings may be normal.¹²⁵ Early changes are symmetrical increased signal intensity in the basal ganglia^{11, 30, 85, 118} and occasionally in the white matter.¹³¹ Occasionally, the changes in the basal ganglia occur before the typical clinical and neurophysiologic signs of CJD develop.¹⁰¹ In three patients, cortical diffusion-weighted imaging abnormalities were reported to occur before the onset of abnormal signal in the basal ganglia on routine sequences.

The year 1986 heralded the appearance of a new form of CJD—bovine spongiform encephalitis (BSE), or "mad cow disease." This new variant (nvCJD) was first detected in humans in 1996. The possibility of direct transmission of BSE from cows to humans has raised serious concerns, especially in Europe.¹²⁷ nvCJD tends to affect a younger population, with a median age at death of 29 years.¹²⁹ The earliest MRI findings are abnormal signal intensity on the long TR-weighted images of the pulvinar.^{129, 132}

During the late stages of the disease, significant atrophy develops and progresses rapidly.¹²⁵ Symmetrical increased T2 signal abnormality with mass effect in the occipital cortex, predominantly in a gray matter distribution, has been reported.³⁸ A study using magnetic resonance spectroscopy (MRS) detected a decrease in *N*-acetylaspartate (NAA) and other metabolites in late CJD.⁵³

Huntington's Disease

Huntington's disease (HD) is a degenerative neurologic disease that is inherited in an autosomal dominant fashion with complete penetrance. It is determined by a gene localized to the short arm of chromosome 4. Patients usually become symptomatic before age 50 and tend to present with abnormalities of affect and personality. Within time, dementia becomes evident, accompanied by gradual disintegration of motor control and the emergence of choreoathetoid movements. Occasionally, rigidity rather than chorea is the most salient motor abnormality (Westphal variant).

Neuropathologically, the most conspicuous finding in patients with HD is atrophy of the basal ganglia, generally proceeding medial to lateral and dorsal to ventral.^{58, 99, 126} Degenerative changes can also affect the frontal and temporal cortices. The degenerative process is accompanied by diminished neurotransmitter concentrations of acetylcholine and gamma-aminobutyric acid (GABA). In early cases, neuronal loss is generally first appreciated in the head of the caudate.¹²⁶ This has been confirmed by a number of MRI studies showing atrophy of the basal ganglia in patients with HD, which is most prominent in the head of the caudate, appearing as focal enlargement of frontal horns on imaging. The atrophy of these structures worsens as the disease progresses.⁹ MRS studies indicate a decrease in

Figure 10-15. Huntington's disease in a 33-year-old man. Axial proton-density (A) and T2-weighted (B) images demonstrate abnormal signal intensity in the putamen and caudate nuclei. (From Sclar G, Kennedy CA, Hill JM: Cerebellar degeneration associated with HIV infection [letter]. *Neurology* 54:1012-1013, 2000.)

NAA and creatine in the basal ganglia of 60% in symptomatic patients and a decrease of 30% in presymptomatic gene carriers.¹¹⁴

A number of investigators have reported that in addition to atrophic changes, patients with HD present with areas of abnormal T2 signal hyperintensity in the basal ganglia (Fig. 10-15). Two groups have reported that such changes are present in all patients with the rigid form of HD but only occasionally in the classic hyperkinetic form.^{93, 107}

More advanced cases of HD present with atrophy of other parts of the central nervous system, including the olives, pons, and cerebellum¹⁰⁸; the thalamus, mesial temporal lobe and white matter tracts⁷⁰; and the cerebral cortex.¹¹⁵ Cortical atrophy, as seen on the MRI scan, has been shown to correlate well with specific neuropsychological deficits.¹¹⁵

Parkinson's Disease

Parkinson's disease (PD) affects approximately 1% of the population over 50 years of age and is perhaps the most common neurologic explanation of progressive motor impairment among older adults. Onset of symptoms is typically seen between 40 and 70 years of age. The disease is caused by an acceleration of the normal age-dependent depletion of dopamine synthesizing pigmented cells within the pars compacta of the substantia nigra. The loss of dopaminergic input to the striatum caused by this cell loss produces a characteristic syndrome, of which the most salient features are progressive bradykinesia, rigidity,

masked facies, hypophonia, festinating gait with stooped posture, and a coarse resting tremor. Dementia may occur in up to 30% of patients, which may reflect the concomitant presence of AD. In addition to the substantia nigra, patients at autopsy reveal a loss of pigmented cells within the locus ceruleus and the dorsal motor nucleus of the vagus. These regions exhibit reactive astrocytosis, and some of the remaining neurons contain eosinophilic cytoplasmic inclusions called Lewy bodies.

Radiographs show a significant narrowing of the pars compacta of the substantia nigra, best visualized on T2-weighted sequences. Multiple studies have demonstrated very little overlap between patients with PD and normal age-matched controls.^{15, 34} Early PD has been reported to show a loss of signal in a lateral to medial gradient of the pars compacta, thereby indicating the potential for detecting presymptomatic disease.⁶³ The diagnostic role of MRI in patients with suspected PD is to exclude other neurodegenerative syndromes with a clinical presentation similar to that of PD.^{17, 110}

With the advent of deep brain stimulator (DBS) implants, which have been successful in treatment of medically refractory tremor, MRI plays an important role in targeting the nucleus ventralis intermedius (Vim) of the thalamus during the stereotactic implantation of the device.⁵

Multiple-System Atrophy

In contrast to PD, in which extrapyramidal clinical manifestations result from a loss of dopaminergic input to the

striatum, other diseases produce progressive motor dysfunction by means of primary degenerative processes that simultaneously affect groups of several subcortical anatomic structures. This group of disorders has been referred to by the clinical term *Parkinson's plus syndrome* or by the anatomic term *multiple-system atrophy* (MSA). Various forms of MSA can present with a clinical picture similar to that of PD. These two disorders can be especially difficult to differentiate clinically early on in the presentation.

Neurologically, MSA is suspected when patients presumed to have PD do not respond to L-dopa therapy. Anatomically, the patient's disease is due to the involutional change undergone by various combinations of striatal, cerebellar, pontine, brain stem, and spinal cord nuclei. With the growing ability of MRI to show detailed anatomy, a number of recent investigators have demonstrated the atrophic and signal abnormality changes in patients with the various forms of MSA, which allows differentiation from PD.

One neuropathologic pattern of MSA is termed *striatonigral degeneration* (SND). In patients with this condition, a PD-like syndrome results from a progressive atrophy and neuronal depletion of the putamen and caudate, accompanied by cell loss within the zona compacta of the substantia nigra without Lewy body deposition. Radiographically, patients with SND also exhibit thinning of the pars compacta of the substantia nigra, a presentation similar to that seen in PD.^{8, 116} This is expected from the histopathology of the disease. However, SND also exhibits a number of specific findings that allows one to differentiate it from PD radiographically.

The most prominent distinguishing feature of SND is the presence of hypointensities in the putamen,^{78, 92, 117, 120, 123} thought to be due to increased iron deposition.^{28, 103} Focal atrophy in the quadrigeminal plate¹⁰⁴ and putamen⁹² has also been reported. These findings are not seen in PD. When MSA patients present with hemiparkinsonism, MRI findings have consistently demonstrated abnormalities, including (1) T2 hypointensity of the posterior lateral putamen and (2) atrophy of the putamen, caudate nucleus, and pars compacta of the substantia nigra on the contralateral side.^{71, 78}

Another form of MSA is olivopontocerebellar atrophy (OPCA) in which degeneration involves the pontine nuclei, transverse pontine fibers, middle cerebellar peduncles, cerebellar cortex, and inferior olives. Clinically, the syndrome results in progressive ataxia and bulbar dysfunction. OPCA is typically a disorder of adult onset and can be both familial (usually autosomal dominant) as well as sporadic.

Radiographically, patients present with atrophy of the transverse fibers of the pons, cerebellum,^{87, 120} and middle cerebellar peduncles¹⁰⁶ (Fig. 10–16). There is a mild decrease in the width of the pars compacta of the substantia nigra.⁹ The T2 hypointensity seen in SND is not seen in OPCA.¹²³ These radiographic findings are in concert with the histopathology. They appear to be specific for the disease and should be identified before the diagnosis of OPCA is made.

Other cases have been identified in which the anatomic loci of degenerative change are even more widespread and involve brain stem motor nuclei, corticospinal pathways, and such spinal cord structures as the dorsal columns,

anterior horns, and spinocerebellar tracts. OPCA can occur independently or in tandem with SND.

Many patients with MSA undergo cell loss within the autonomic intermediolateral nuclei of the spinal cord, producing symptoms of orthostatic hypotension, anhidrosis, incontinence, and sexual dysfunction in addition to the those of MSA. This is known as *Shy-Drager syndrome* (SDS). MRI findings reflect the atrophic changes and T2 abnormalities seen in MSA.^{96, 105}

Progressive Supranuclear Palsy

Progressive supranuclear palsy (PSP) is a neurodegenerative disorder without known familial predilection that affects middle-aged and older adults. The pathologic changes involve neuronal loss and astrogliosis within the globus pallidus, dentate nucleus, and several diencephalic structures, including the subthalamic nucleus, periaqueductal gray matter, and pretectal regions. Single-stranded neurofibrillary pathology is a distinctive histopathologic feature of this condition. The clinical presentation is characterized by pseudobulbar signs, supranuclear oculomotor disturbances, axial dystonia, gait dysfunction, and dementia.

Radiographically, patients with PSP present with atrophy of the pretectum, dorsal pons, tectum and midbrain.⁴ In addition, decreased T2 relaxation times have been reported in the superior colliculi, globus pallidus, and putamen, which are more pronounced than in patients with MSA.³³ These radiographic findings are confirmed by the histopathology of the disease and are useful in distinguishing PSP from clinically similar entities such as PD.^{33, 109}

Friedreich's Ataxia

Friedreich's ataxia (FA) is a progressive spinocerebellar degeneration transmitted both by autosomal dominant and recessive modes of inheritance that affect both children and young adults. Spinal cord degeneration involves the dorsal columns, lateral corticospinal tracts, Clarke's column, and spinocerebellar tracts. Degeneration also occurs within the dorsal root ganglia, dentate nucleus, cerebellar vermis, and inferior olive. Children typically present with ataxia and are often incapable of walking by 5 years of age. Later, bilateral Babinski signs with areflexia, tremor, slurred speech, and nystagmus appear. Other associated abnormalities include pes cavus deformity, kyphoscoliosis, and cardiomyopathy.

Radiographic findings include FA spinal cord atrophy, which is often severe¹²⁸ and which is seen even in early cases.⁸⁹ Moderate cerebellar or bulbar atrophy is occasionally seen.¹²⁸ In advanced cases, atrophy of the cerebellar vermis and medulla has been reported (Fig. 10–17).⁹⁴

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), is the most common form of a broader class of motor system diseases characterized by primary degeneration of the motor neurons within the brain, brain stem, and spinal cord. Patients

Figure 10-16. Olivopontocerebellar atrophy in a 57-year-old woman who presented with slight unsteadiness 2 years earlier. The symptoms have since progressed. At the time of this MRI study, she was experiencing swallowing difficulties, abnormal eye movements, and severe difficulty walking. Sagittal T1-weighted (A), axial T1-weighted (B), and two axial T2-weighted (C and D) images demonstrate atrophy of the transverse fibers of the pons, the cerebellum, the middle cerebellar peduncles, and the inferior olives. E, Axial T2-weighted image through the lateral ventricles fails to demonstrate atrophy or hydrocephalus. (From Holodny AI, George AE, Gomb J: Neurodegenerative disorders. In Edelman R, Hesselink JR [eds]: Clinical Magnetic Resonance Imaging, 2nd ed. Philadelphia, WB Saunders, 1996.)

typically present with progressive muscle weakness and limb and truncal atrophy combined with signs of spasticity. Mean age at the time of diagnosis is 55 years, and the incidence of new cases is 1 per 100,000 population.¹⁸ Familial transmission is seen in 10% of the cases as both

autosomal dominant and recessive traits and sporadic in the remaining 90% of the cases.¹¹² Prognostically, about 50% of patients die within 3 years and 90% die within 6 years following onset of symptoms.

In ALS, both anterior horn neurons in the spinal cord

Figure 10-17. Progressive Friedreich's ataxia in a 4-year-old girl. Two sagittal (A and B) and two axial (C and D) T1-weighted images demonstrate severe atrophy of the cerebellum. (From Holodny AI, George AE, Golomb J: Neurodegenerative disorders. In Edelman R, Hesselink JR [eds]: Clinical Magnetic Resonance Imaging, 2nd ed. Philadelphia, WB Saunders, 1996.)

as well as pyramidal Betz cells within the primary motor cortex (precentral gyrus) undergo progressive involuntional change. Histopathologic features include astrocytosis, lipofuscin deposition, and, occasionally, the accumulation of intracytoplasmic inclusion bodies. Secondary degeneration of the descending corticospinal fibers occurs with variable demyelination and lipid-filled macrophage buildup. Corticospinal tract involvement is most evident within the lateral and anterior columns of the lower spinal cord but can also affect the cerebral white matter of the internal capsule, corona radiata, and centrum semiovale.

MRI reveals abnormal signal intensity along the motor pathways. In the precentral gyrus (i.e., the location of the perikarya of the motor neurons, which are affected by ALS), T2 hypointensity is thought to represent increased deposition of iron.^{91, 130} In the subcortical white matter tracts, patients with ALS typically demonstrate abnormal hyperintensity on long TR images (T2, proton-density, and FLAIR). These areas of signal abnormality extend from the motor cortex to the centrum semiovale, the corona

radiata, the posterior third quarter of the internal capsule, and the pons.^{1, 51, 65, 66, 124} Radiologic-pathologic studies have shown that these signal abnormalities represent degeneration of the corticospinal tract and myelin pallor.⁶⁵ These signal abnormalities are distinctly different from normally appearing areas of hypointensity on T1 and hyperintensity on T2, which represent normal fibers of the corticospinal tract traversing the internal capsule. Similar areas of T2 hyperintensity have been identified in the corticospinal tracts in the spinal cord.³⁹

MRI shows an increase in the mean choline and myo-inositol and a decrease in glutamine and *N*-acetyl in the precentral gyrus.¹³ Magnetization transfer measurements have also been reported to be sensitive in the early identification of ALS.⁷¹

Brain Magnetic Resonance Spectroscopy

Jay J. Pillai, Lester Kwock

A Brief History

Magnetic resonance spectroscopy (MRS) is a means of noninvasive physiologic imaging of the brain that measures relative levels of various tissue metabolites. Absolute quantitation of these metabolites is also possible, although in standard clinical practice ratios are commonly used to describe relative concentrations of these metabolites. MRS enables evaluation of metabolic derangements that are specific to certain central nervous system (CNS) diseases or categories of disease. Thus, MRS may aid in the diagnosis of various CNS diseases when standard structural magnetic resonance imaging (MRI) findings may be nonspecific. MRS may also be used to monitor therapy and to provide prognostic information in certain conditions. This chapter presents the basic principles of MRS, followed by a discussion of basic clinical applications.

The discovery of the phenomenon of nuclear magnetic resonance (NMR) can be traced to Purcell and coworkers and Bloch and coauthors in 1946, who found that magnetic dipoles of atomic nuclei resonated when placed in an external magnetic field and demonstrated nuclear induction (induction of an electromotive force in a surrounding recording coil).^{20, 116, 185} MRS, in the 1970s, involved phosphorus (³¹P) spectroscopy in animals, including evaluation of red blood cells and rat leg muscle tissue.^{101, 116, 161} Human applications became possible in the early 1980s, when larger-bore magnets became available; applications in the extremities were followed by applications in the CNS.¹¹⁶ The first human brain applications involved ³¹P spectroscopy in infants.^{32, 99, 116, 197} Bottomley and Radda and their coauthors then described applications of in vivo ³¹P spectroscopy in the adult brain, followed in 1985 by the earliest in vivo brain hydrogen (¹H) spectroscopic studies.^{22, 23, 116, 186}

With the advent of technical advances that allowed for improved spatial localization and water suppression, MRS has rapidly progressed in clinical utility and acceptance in the late 1980s to near its current status. Today MRS—in particular, ¹H MRS—has become a valuable physiologic imaging tool with wide clinical applicability.

Technical Considerations

Basic Principles

What is the difference between MRS and MRI? The answer to this most frequently asked question is that basi-

cally there is no difference, because both techniques are governed by the same physical principles of magnetism. MRS and MRI differ only in the manner in which the data are processed and presented. With MRI, the data collected are analyzed in the time domain (free induction decay [FID] signal) to obtain information about the nuclear relaxation time (namely, T1 and T2), which is processed to generate an anatomic image. In MRS, time domain information is converted to frequency domain information via Fourier transformation of the FID time domain signal.

What is the frequency domain, and why do the protons of water resonate at a different frequency (H₂O, 4.7 parts per million at pH = 7.4) from that of the protons located in other metabolites, such as the following?

1. The *N*-acetyl methyl group of *N*-acetylaspartate (CH₃C=ONH—R; 2.0 ppm).
2. The *N*-methyl groups of choline ((CH₃)₃N—); 3.2 ppm).
3. The *N*-methyl group of creatine (CH₃—NH—R).

As presented in a number of reviews, NMR is based on the principle that some nuclei have associated magnetic spin properties that allow them to behave like small magnets.^{123, 206, 213} In the presence of an externally applied magnetic field, the magnetic nuclei interact with that field and distribute themselves to different energy levels. With protons having a magnetic spin number of 1/2, the nuclei distribute themselves into two energy states. Conceptually, these energy states correspond to the proton nuclear spins, either aligned in the direction of (low-energy spin state) or against the applied magnetic field (high-energy spin state).

If energy is applied to the system in the form of a radiofrequency (RF) pulse that exactly matches the energy between both states, a condition of *resonance* occurs. That is, nuclei in the lower-energy state can absorb this energy and are promoted to the higher-energy state. The Larmor frequency equation describes this phenomenon:

$$\Delta E = h\omega_0 = h/2\pi\gamma B_0$$

where

ω_0 is the Larmor precessional frequency (cycles/second [Hz])

h is Planck's constant

γ is the gyromagnetic ratio for that nucleus (MHz/Tesla [T])

B_0 is the applied magnetic field (T)

This equation states that the resonance frequency of a

magnetic nucleus (the RF needed to excite a given nucleus to the higher spin state) is directly proportional to the magnetic field environment it experiences. Chemical elements having different atomic numbers such as hydrogen (^1H) and phosphorus (^{31}P) resonate at different Larmor RFs because of the differences in the magnetic properties in the nucleus of these atoms; that is, at 1.5 T the Larmor RF for ^1H is 63.86 MHz; for ^{31}P it is 25.85 MHz.

This difference in the Larmor RF has been used to identify magnetic nuclei having different atomic numbers. Even for a given magnetic nucleus having the same atomic number, however, chemical compounds containing this nucleus can have slightly different Larmor RFs. The reason for this is due to the electrons (negatively charged subatomic particles) that surround the nucleus of the atom. The circulating electrons form an "electron cloud" that surrounds the nucleus. Like protons and neutrons in the nucleus of the atom, electrons have magnetic spin properties. Thus, when exposed to an externally applied magnetic field, electrons precess and produce a small magnetic field, B^* , around the nucleus. These local magnetic fields generated by the electrons (normally in the range of parts per million of B_0) can add or subtract from the applied magnetic field, B_0 . Consequently, the nucleus of the atom experiences a slightly different magnetic field from B_0 . This field is defined as $B_{\text{effective}}$ and is equal to $(B_0 - B^*)$.

Because of this small change in the local magnetic field, the nucleus of the atom resonates at a shifted Larmor RF; i.e.,

$$\Delta E = h2/\pi (B_0 - B^*) = h(\omega_0 - \omega^*)$$

This phenomenon is called the chemical shift and is the basis of MRS.

Single-Volume versus Multivolume MRS Techniques

Single-Volume Proton Magnetic Resonance Spectroscopy

At present, two single-volume proton localization techniques are employed in clinical MRS studies²⁴:

- Stimulated echo acquisition mode (STEAM)
- Point-resolved spectroscopy (PRESS)

Both methods are highly effective, each with its advantages and disadvantages.

Advantages of STEAM

STEAM enables observation of proton metabolites that have short T2 relaxation processes, such as *myo*-inositol (MI), glutamate (Glu), and glutamine (Gln), because echo times (TEs) less than 20 msec can be used; with PRESS, they cannot. STEAM also affords more effective suppression of the water resonance signal because water suppression *chemical shift-selective* (CHESS) pulses can be placed not only at the preparation phase of the volume localization pulse sequence but also within the localization sequence (at the TM phase of the STEAM sequence) without penalty to the TE being used. This is a major advantage, especially when short TEs (<20 msec) are used. At short TEs, the

signal intensity of the water resonance can be severalfold greater than at higher TEs; thus, higher or more water suppression pulses must be used to attenuate the water signal.

In PRESS, the water suppression CHESS pulses can be placed only at the beginning of the localization pulse sequence.

Disadvantages of STEAM

There are two major disadvantages of STEAM:

1. There is a theoretical factor-of-2 loss in signal intensity.
2. STEAM is much more susceptible to motion, multiple quantum effects (i.e., homonuclear coupling), and diffusion processes that lead to difficulties in phasing and baseline corrections in the spectrum.¹⁶²

The twofold signal loss in signal intensity in the STEAM sequence is due to the imperfect refocusing of the spin magnetization when the second 90-degree pulse is applied, which rotates only half the spins of interest into the longitudinal axis; this part of the magnetization eventually generates the stimulated echo. The other half of the spin magnetization that remains in the transverse axis is dephased by the TM spoiling gradient and does not lead to any rephased magnetization at the time of acquisition.

Advantage of PRESS

The major advantage of the PRESS sequence is the theoretical twofold gain in signal intensity compared to the STEAM sequence. PRESS is also much less sensitive to patient motion, homonuclear coupling effects, and eddy current effects.¹⁶²

Multivolume Magnetic Resonance Spectroscopy

Multivolume MRS is normally called either *chemical shift imaging* (CSI) or *spectroscopic imaging* (SI) because the signal intensity, peak resonance areas, or ratios of peak areas or signal intensities of the metabolites can be converted to an image format and overlaid onto anatomic magnetic resonance (MR) images, thus showing a qualitative or quantitative distribution of the metabolite within the brain area examined.¹⁷⁹ Utilizing the CSI/SI multivolume technique, one can obtain spectroscopic information from multiple adjacent volumes over a large region of interest in a single measurement. Volume elements as small as 1 mL can be examined in reasonable acquisition times, namely, 6 to 12 minutes.^{26, 74, 250}

The MRS pulse and gradient sequences used to obtain the localized multivolume spectroscopic data are similar to MRI sequences except that no readout gradient is applied during the data collection.¹³² Either PRESS or STEAM pulse sequences are used for volume selective pulse sequences for the CSI/SI multivolume technique, which defines a large slice. Spatial localization is achieved by phase encoding in one dimension (1D CSI/SI), two dimensions (2D CSI/SI), or three dimensions (3D CSI/SI):

The 1D CSI/SI generates a column of n volume elements within the defined slice (n = number of phase-encoding steps in a defined phase-encoding direction).

The 2D CSI/SI generates $n_1 \times n_2$ adjacent volume elements within a defined slice plane.
The 3D CSI/SI generates multiple defined adjacent slice planes with $n_1 \times n_2 \times n_3$ spectroscopic volume elements or voxels.

Practical Considerations in Spatially Localized Magnetic Resonance Spectroscopy

Suppression of Water Peak in Localized Proton Magnetic Resonance Spectroscopy

The concentration of protons of water is 110 molar, whereas the concentrations of tissue proton metabolites are typically in the millimolar concentration range. This difference in concentration between water protons and tissue metabolites leads to a large dynamic concentration range effect on the observed signal intensity in the MR spectrum.

If the water peak is not suppressed or attenuated, the spectrum is dominated by the water resonance and no other resonances can be observed. This is due to the fact that when the analogue-to-digital conversion of the time domain signal occurs within the receiver of the spectrometer, the intensity of the peaks are scaled relative to the most intense signal found in the frequency domain. Thus, because of the large difference in the concentrations between water and tissue metabolites, if the water signal is not selectively suppressed or attenuated, only the water signal will be observed.

Additionally, a water suppression pulse sequence that only partially suppresses the water signal can lead to residual eddy current effects that can severely distort the phase of the signals and baseline of the spectrum. These distortions may not be corrected for by the postprocessing procedures used to correct for the phase of the signals and the baseline of the spectrum and thus will render the spectrum uninterpretable.

One usually accomplishes suppression of the water peak by using a frequency-selective pulse, centered over the resonance frequency of the water protons, and increasing the amplitude of this pulse until maximal attenuation of the water peak is achieved via a peak saturation process. The water-selective frequency pulse is applied before the beginning of the volume localization pulse sequence.¹³²

Field Homogeneity

The magnetic field homogeneity of the volume being analyzed should be as uniform as possible. In most cases, the water shim should be less than 0.2 ppm (~12 Hz at 1.5 T), as judged by measuring the width of the water signal at half-peak height.

Inhomogeneities in the magnetic field of the volume lead to slightly different Larmor frequencies for proton nuclei from the same molecule in different parts of the volume. This leads to observation of broader peak signals because the signal observed is an average of the peak signal at different Larmor frequencies throughout the volume. This line broadening is undesirable because it not only reduces the signal to noise ratio but also can make it

more difficult to distinguish between two closely neighboring resonance peaks. This can lead to errors in determining peak areas or signal intensities used for quantification of metabolite levels.

Choice of Echo Time

In MRI, the contrast observed in the anatomic images is dependent on the TE and the time between repetition times (TRs) used. If a short TE and a long TR are used, the image contrast becomes more dependent upon the total number of spins or density of protons in each pixel. If a long TE and TR are used, the contrast in each pixel forming the image is more dependent on the T2 or spin-spin relaxation time of the proton nuclei.

Similarly, in MRS, changing the TE changes the type of information obtained as well as the appearance of the frequency domain spectrum. *The choice of TE or TEs to be used should be decided by the clinical question being asked.*

For instance, if a patient is thought to have Alzheimer's disease, MRS should be performed using a short TE (<30 msec), because the *myo*-inositol/creatine (MI/Cr) ratio would be significantly elevated in this patient.²¹⁷ MI can be observed with only short TEs.

To determine whether a hypoxic event is occurring, a TE = 135 msec should be used because the major question is whether lactate (Lac) is present. At a TE of 135 msec, an inverted doublet should be observed in the spectrum centered at 1.3 ppm, which suggests the presence of Lac.²⁴⁴

Finally, to determine whether the lesion is a tumor, a TE of 270 msec should be used because we are interested in examining differences in the *N*-acetylaspartate/creatine (NAA/Cr) and choline/creatine (Cho/Cr) ratios. At this long TE, differences between NAA, Cho, and Cr signal intensities are maximized because of the differences in the concentration of these metabolites and T1 relaxation times in tumor versus normal tissue.¹⁸³

Clinical Applications of Proton Magnetic Resonance Spectroscopy

Important Metabolites

Several important metabolites are evaluated in long TE (135 to 288 msec) proton MR spectra (Fig. 11-1):

- *N*-acetylaspartate (NAA)
- Choline (Cho)
- Creatine/phosphocreatine (Cr)
- Lactate (Lac)

When short TEs (20 to 30 msec) are used, a greater number of metabolites can be identified in the MR spectra; in addition to NAA, Cho, Cr, and Lac, the following may be identified^{18, 35, 102, 163, 182, 193, 200, 251}:

- Glx (glutamate [Glu])
- Glutamine (Gln)
- Gamma-amino butyric acid (GABA)
- MI
- Alanine (Ala)
- Glucose (Gc)

Figure 11-1. Normal adult brain, proton MR spectra. Example of normal single-voxel spectra obtained with echo time (TE) values of 20 and 270. Asp, aspartate; Cho, choline; Cr, creatine; Myo, *myo*-inositol; NAA, *N*-acetylaspartate.

- Lipids and proteins
- Scyllo-inositol/taurine (scyMI/Tau)

Although it may appear advantageous to obtain spectra routinely at only short TEs to distinguish among different clinical entities, some disadvantages of short TE studies exist. For example, short TE spectra display greater baseline distortion, and estimating peak areas calls for more sophisticated processing software algorithms.¹⁶⁹ Methods of absolute measurement of peak areas have been developed and are rapidly gaining acceptance; however, most proton MR spectra today are described in terms of metabolite ratios, with creatine often used as the reference standard.¹⁴

NAA

NAA accounts for the majority of the NAA resonance at 2.01 ppm; this peak is the most prominent one in normal adult brain proton MRS and is used as a reference for determination of chemical shift.^{12, 125, 126} The NAA peak also contains contributions from other *N*-acetyl groups, such as *N*-acetylaspartylglutamate (NAAG), glycoproteins, and amino acid residues in peptides.^{12, 125, 126} NAA is second only to Glu as the most abundant free amino acid in the normal adult brain.¹⁴⁴ The function of this amino acid is not fully understood despite its early discovery in 1956 by Tallan.^{229, 230}

From animal studies, NAA is believed to be involved in coenzyme A (CoA) interactions and in lipogenesis within the brain.^{8, 16, 29, 60} Specifically, such studies suggest that NAA is synthesized in the mitochondria from aspartate and acetyl CoA and transported into the cytosol, where it is converted by aspartoacylase into aspartate and acetate.^{16, 40, 60} Although NAA is widely regarded as a nonspecific neuronal marker, it has also been detected in immature oligodendrocytes and astrocyte progenitor cells.^{200, 243}

Normal absolute concentrations of NAA in the adult brain are generally in the range of 8 to 9 mmol/kg, although regional and age-related variations in NAA concentration have been noted by Kreis and others.^{127, 153, 182} In normal adults, NAA concentrations in cortical gray matter are higher than those in white matter; in infants, the concentrations in gray and white matter are similar (highly active lipid synthesis in immature white matter accounts for this difference from the adult pattern).^{29, 157} NAA concentrations are decreased in many brain disorders, resulting in neuronal and/or axonal loss, such as in neurodegenerative diseases, stroke, brain tumors, epilepsy, and multiple sclerosis, but are increased in Canavan's disease.²¹

Creatine

The main Cr peak is present at 3.03 ppm and demonstrates major contributions from methyl protons of creatine and phosphocreatine as well as minor contributions from GABA, lysine, and glutathione.^{125, 126} A second, usually smaller Cr peak is seen at 3.94 ppm. Cr is probably involved in maintenance of energy-dependent systems in brain cells by serving as a reserve for high-energy phosphates in muscle cells and neurons and as a buffer in cellular adenosine triphosphate/diphosphate (ATP-ADP) reservoirs.^{38, 40, 127, 155} Thus, this Cr peak is an indirect indicator of brain intracellular energy stores.

The Cr peak is often used as an internal reference standard for characterizing other metabolite signal intensities, because it tends to be relatively constant in each tissue type in normal brain; however, this is not always true in abnormal brain tissue, particularly in areas of necrosis.¹³⁹ Cr concentrations in the brain are relatively high, with progressive increases noted from white matter to gray matter to cerebellum.^{182, 200} Kreis and coworkers noted a mean absolute Cr concentration in normal adult brains of 7.49 ± 0.12 mmol/kg on the basis of a sample of 10 normal subjects,^{127, 202} whereas Michaelis and colleagues reported a similar value of 5.3 mmol/kg.^{115, 153} Cr values tend to be abnormally reduced in all brain tumors, particularly malignant ones.³⁶

Choline

The Cho resonance is present at 3.2 ppm and is attributable to trimethylammonium residues of free choline as well as phosphocholine, phosphatidylcholine, and glycerophosphocholine. This peak reflects cell membrane synthesis and degradation.²¹ Thus, all processes resulting in hypercellularity (e.g., primary brain neoplasms or gliosis) or myelin breakdown (demyelinating diseases) lead to locally increased Cho concentration, whereas hypomyelinating diseases result in decreased Cho levels.^{21, 36} Kreis and coworkers have described a mean absolute Cho concentration in normal adult brain tissue of 1.32 ± 0.07 mmol/kg.^{127, 202} Michaelis and others have reported a similar value of 1.6 mmol/kg.^{115, 153}

Myo-inositol

MI produces two peaks, noted at 3.56 ppm and 4.06 ppm. MI is the major component of the peak at 3.56 ppm, although contributions from MI-monophosphate and glycine are also present.¹⁹³ MI is believed to be a glial marker because it is present primarily in glial cells and is absent in neurons.²⁵

A role in osmotic regulation of the brain has been attributed to MI.²⁰⁰ In addition, MI may represent both a storage pool for membrane phosphoinositides involved in synaptic transmission and a precursor of glucuronic acid, which is involved in cellular detoxification.^{35, 38, 104, 128} A derivative, MI-1,4,5-triphosphate, may act as a second messenger of intracellular calcium-mobilizing hormones.^{38, 43}

The mean absolute concentration of MI in normal brain tissue obtained in the Kreis series was 6.56 ± 0.43 mmol/kg.^{127, 198} MI concentrations are abnormally increased in patients with demyelinating diseases and in those with Alzheimer's disease.^{38, 153}

Lactate

Lac resonance is identified as a doublet (splitting into two distinct resonant peaks separated by 0.2 ppm, produced by magnetic field interactions among adjacent protons (referred to as J-coupling) centered at 1.32 ppm. A second Lac peak is present at 4.1 ppm but tends to be inconspicuous on spectra obtained with water suppression owing to its proximity to the water peak.³⁸ Because Lac levels in normal brain tissue are absent or extremely low (<0.5 mmol/L), they are essentially undetectable on normal spectra.²⁰⁰ The presence of a visible Lac peak constitutes a

nonspecific indicator of cellular anaerobic glycolysis, which may be seen with brain neoplasms, infarcts, hypoxia, metabolic disorders, or seizures.²⁰⁰ Lac may also accumulate within cysts or foci of necrosis.^{38, 200}

Changing the TE using a PRESS sequence enables confirmation of the presence of an abnormal Lac doublet and differentiation from lipid peaks; at TE = 272 msec, the Lac doublet projects above baseline; at TE = 136 msec, the doublet is inverted below the baseline.³⁸ In encephalopathic neonates, however, a doublet very similar to Lac may be seen at 1.15 ppm, which corresponds to propan-1,2-diol and which may be easily mistaken for Lac; propan-1,2-diol is a solvent commonly used for administration of anticonvulsant medications to neonates.¹⁴

Glutamate, Glutamine, and GABA

The Glx peaks are a complex set of resonances noted between 2.1 and 2.5 ppm and consist of Glu, Gln, and GABA components. Glutamate is an excitatory neurotransmitter involved in neuronal mitochondrial metabolism and is the most abundant amino acid in the human brain.^{38, 40, 247} Glutamine is involved in both cellular detoxification and regulation of neurotransmitter activities.^{38, 153} GABA is a product of Glu and serves as an inhibitory neurotransmitter.²⁰⁰ Abnormalities in this peak complex have been noted in schizophrenia and epilepsy.⁴⁰

Alanine

The Ala resonance is present between 1.3 and 1.5 ppm and is easily overshadowed by the Lac resonance when also present. Ala is a nonessential amino acid with no known specific function.^{38, 200} However, its elevation is frequently noted in meningiomas.³⁵

Fats and Proteins

Lipids produce multiple resonances, the most important of which are noted at 0.8 to 0.9 and 1.2 to 1.3 ppm because of methyl and methylene protons, respectively.^{38, 110, 181, 200} Membrane lipids are not usually identified unless very short TEs are employed, since they have very short relaxation times.³⁸ Although artifactual accentuation of these peaks may be seen with voxel contamination by adjacent subcutaneous fat, it may also be noted in high-grade gliomas, meningiomas, demyelination, necrotic foci, and inborn errors of metabolism.²⁰⁰

Scyllo-inositol

Scyllo-inositol is a nonmetabolized isomer of MI that may inhibit the incorporation of MI into phospholipids. It demonstrates a single peak at 3.35 ppm.¹⁴ Most authorities in the field believe that this peak results from scyllo-inositol rather than from taurine (Tau), as had been thought in the past.¹⁴

Normal Brain Development During Childhood

Although most neurons are formed during intrauterine life, proliferation of dendrites, astroglia, and oligodendroglia

continues after birth.²¹² In particular, the processes of myelination and neuronal and dendritic development are associated with changes in various brain metabolites during infancy and early childhood, which are demonstrated by MRS.^{107, 118, 127, 245}

NAA is present in very low concentrations in the newborn brain, compared to those in the adult brain, but levels rapidly increase during the first 2 to 3 years of life and may even double according to one study.¹⁰⁷ Preterm infants were noted to have lower brain NAA levels than full-term infants.²⁰⁰

MI forms the most prominent peak in the newborn MR spectrum, whereas Cho dominates the spectrum of older infants.²¹ The reason for the prominence of these two components of the infant spectrum is presumed to be the presence of active myelination.²¹² In fact, MRS may enable earlier detection of white matter myelination abnormalities in infants than is possible with conventional MRI sequences because changes in the Cho and NAA peaks occur before white matter signal abnormalities on standard imaging sequences.²¹²

Although NAA and Cr levels increase during the first few weeks of life, Cho and MI levels decrease.²¹ In fact, the MI peak declines rapidly in the first 3 to 4 months and decreases to adult levels by approximately 1 year of age.²⁰⁰ Cr levels rise to adolescent levels by 4 months of age, presumably as a result of increasing energy demands of the developing brain.^{187, 237} The spectral pattern stabilizes during early adulthood, and NAA levels then begin to decrease with advancing age.²¹

The Cr/Cho ratio increases in gray matter during the first 2 years of life, whereas the ratio remains nearly constant in white matter.¹⁴ The scyllo-inositol peak is also highest in newborns and decreases over time.^{96, 104, 152}

Lac peaks are normally seen in preterm and small-for-gestational-age infants.^{14, 200} However, in appropriate-for-gestational-age term infants, it is abnormal to find higher than trace amounts of Lac, particularly following the first few hours of life; such abnormal amounts of Lac signify brain injury.¹⁴ In preterm infants, the levels of Lac decrease progressively until the age of 40 postconceptional weeks.^{14, 136, 176}

Significant regional heterogeneity in spectral patterns has been noted in both the developing brain and in mature brains.^{4, 83, 255} In the developing brain, proton MR spectra demonstrate that different parts of the brain mature at different rates and at different times and that the more metabolically mature areas demonstrate lower MI and higher NAA levels than those in less mature regions of brain; specifically, the basal ganglia, perirolandic cortex, and visual cortex mature before areas such as the prefrontal cortex and temporal cortex.^{14, 108, 140}

Tedeschi and colleagues²³² have noted significant regional variations in metabolite ratios in young adults; NAA/Cho and NAA/Cr ratios varied by more than a factor of 2 for different brain regions with particularly high levels of Cho and Cr and low levels of NAA found in the cerebellar vermis.²⁵⁵ In addition, Ando and coworkers noted that NAA/Cho ratios in the frontal region were lower than those in the parietal lobe at birth with subsequent increase during the first 6 months of life.⁴

Grachev and Apkarian have demonstrated metabolic

heterogeneity in normal brain tissue that appears to be age-dependent and gender-dependent as well as specific for brain region.⁸³ For example, in their series they noted that the total metabolite concentrations were highest in the prefrontal regions in all subjects studied and that higher metabolite concentrations were present in the orbital frontal cortex and sensorimotor cortex in the 25- to 31-year age group than in the 19- to 20-year age group.⁸³ Furthermore, they observed that women demonstrated higher metabolite concentrations in these two areas than men did.⁸³

Brain Tumors

To date, a wide variety of brain tumors have been studied with MRS, and the numerous studies published in this area have demonstrated certain consistent patterns of metabolic abnormalities in both glial and nonglial tumors.* Proton MRS allows reliable differentiation of tumor margins from adjacent brain parenchymal edema, which is not possible with conventional gadolinium-enhanced MRI.³⁶ In fact, conventional MRI underestimates or overestimates tumor size in approximately 40% of cases.¹⁷²

Although it is possible to clearly distinguish glial neoplasms from normal brain tissue by MRS, controversy exists regarding the reliability of MRS in distinguishing among different histologic grades of astrocytomas and other brain tumors.^{38, 129, 168, 215} For example, Shimizu and associates²¹⁵ demonstrated that through semiquantitation of MRS peak intensities as a ratio to that of an external reference, it was possible to predict tumor malignancy; higher-grade brain tumors were associated with higher Cho/reference and lower NAA/reference values in their series.²²⁰

In another series involving children, linear discriminant analysis and proton MRS demonstrated an 83% success rate in establishing the correct diagnosis of histologic grade of brain tumors.²⁵³ In their series of 27 patients with biopsy-confirmed brain tumors, Meyerand and colleagues¹⁵⁰ showed that the combination of Lac/water and choline/water ratios obtained from regions of contrast-enhancing brain tumor (with normalization of each metabolite peak area to the area of the unsuppressed water peak) permitted differentiation of low-grade astrocytomas from anaplastic astrocytomas and glioblastoma multiforme (GBM). In a multicenter study involving 86 cases of glial tumors, however, Negendank and coauthors showed that each type and grade of tumor was a metabolically heterogeneous group with significant overlap in spectral NAA/Cr and Cho/Cr ratios with tumors in other categories; all tumors demonstrated abnormally decreased NAA/Cr and increased Cho/Cr ratios with respect to normal brain parenchyma.¹⁶⁸

Burtscher and colleagues have described a series of 26 intracranial tumors in which MRS allowed differentiation of infiltrative processes from circumscribed lesions but did not allow differentiation of different types of lesions within each category.³⁰

Astrocytomas typically demonstrate reduced NAA levels, moderately reduced Cr levels, and elevated Cho levels compared to normal brain parenchyma²⁷ (Figs. 11–2 to 11–4). These absolute reductions result in abnormally low

NAA/Cr ratios and elevated Cho/Cr ratios.²⁰⁰ In fact, the NAA level in astrocytomas is reduced to 40% to 70% of that of normal brain parenchyma.¹⁴⁸ Furthermore, Cho has been reported to be substantially elevated in the more malignant astrocytomas, and this elevation may reflect increased cellularity and cell membrane synthesis.^{148, 245} There is evidence to suggest that the elevation of Cho is proportional to the degree of tumor malignancy.³⁶ However, highly malignant primary brain tumors with extensive necrosis may actually demonstrate decreased levels of Cho. Elevated Cho levels are seen more consistently in anaplastic astrocytomas, which do not demonstrate histologic evidence of necrosis, than in GBM, and ependymomas display higher Cho/Cr ratios than those noted for astrocytomas in general.^{36, 253}

Lac levels may be elevated in some astrocytomas as well. However, a higher incidence of Lac in more aggressive or higher-grade astrocytomas is controversial because Lac may also be present in benign pilocytic astrocytomas.^{74, 111, 168, 172, 242} It is thought that Lac may be present across the entire spectrum of grades of astrocytomas because Lac may arise not only from hypoxia developing within the tumor itself as a result of disruption of normal vascular networks but also from necrosis or cysts within the tumor.^{36, 38, 215} In fact, Lac levels may be elevated in all cysts regardless of etiology.³⁶

The presence of Lac has been attributed to (1) the extent of anaerobic glycolysis, (2) the efficiency of electron transport, and (3) the rate of washout from tumor tissue.^{111, 138, 200} In highly vascular tumors, Lac may be rapidly removed from the tumor as a result of increased blood flow; even in high-grade vascular tumors, therefore, Lac may not be present in the MR spectra.³⁶

The value of Lac identification following radiation therapy or surgery is controversial, but the Lac concentration may be proportional to tumor size.^{36, 236} Lac has been reported following radiation therapy and surgery, including stereotactic biopsy, although postsurgical porencephaly may lead to artifactual increases in Lac levels, since cerebrospinal fluid (CSF) is known to be rich in Lac.^{36, 74, 141}

The presence of elevated lipid levels has also been used to differentiate low-grade from high-grade neoplasms.^{138, 168, 172, 181, 242} Some studies suggest that mobile lipids tend to be present in higher-grade neoplasms, with highest levels noted in GBM; however, although high levels of mobile lipids may be specific for anaplastic astrocytoma or GBM, their absence in MR spectra does not exclude the possibility of such high histologic grades.¹⁶⁸ Lipids may originate from tumor cells within high-grade astrocytomas, macrophages along the tumor periphery, or areas of necrosis.³⁶ Lipids may be present as a result of microscopic cellular necrosis, which may not be apparent on conventional MR images.³⁶

It must be understood that in adults the biologic behavior of low-grade astrocytomas with identical histologic grades is heterogeneous, with more than half of low-grade tumors eventually recurring as or evolving into more aggressive tumors.¹⁶⁴ Some investigators believe that differences in MR spectral ratios of various metabolites, like differences in glucose metabolism in positron emission tomography (PET), may be of prognostic significance even if they are not of diagnostic value in such cases of low-

*See References 36, 38, 63, 111, 168, 172, 180, 183, 200, 215, 221, 225, 241, 242, and 252.

Figure 11-2. Low-grade glioma. A representative single-volume proton MR spectrum of a histologically proven low-grade glioma was examined using a STEAM (stimulated echo acquisition mode) sequence for the TE = 20 msec spectrum and a PRESS (point-resolved spectroscopy) sequence for the TE = 270 msec spectrum. The TR used was 1500 msec in both the TE = 20 and the TE = 270-msec studies. Note the intensity of the *myo*-inositol (3.56 ppm) and choline (3.2 ppm) resonances at a TE = 20 msec in the low-grade lesions compared to the higher-grade lesions.

grade neoplasms.^{98, 117, 168, 173} In addition, proton MRS may be used to monitor responses of astrocytomas to therapy^{38, 245} (Figs. 11-5 to 11-7). Proton MRS may allow detection of tumor recurrence before abnormalities can be identified on conventional MRI.³⁸

Meningiomas have also been studied extensively with proton MRS, and they display certain characteristic features on MR spectra. Marked elevation of Cho levels up to 300 times that of normal brain parenchyma has been reported, particularly in recurrent meningiomas.^{36, 38, 129} The Cho/Cr ratio has been reported to be higher in malignant meningiomas than in benign meningiomas.^{36, 172}

Theoretically, NAA is not present in meningiomas,

which arise from arachnoid structures and not from within the CNS; however, in clinical experience it is not uncommon to detect NAA in these extra-axial tumors, particularly in atypical and malignant varieties.^{27, 36, 38, 79} The reason for the presence of NAA in these tumors may be contamination of the voxel by adjacent normal brain parenchyma, use of large voxels, or inadequate voxel placement.³⁶ In addition, mobile lipids have been reported in meningiomas, and this may be due to fatty degeneration or contamination of the MRS voxel from subcutaneous tissues or fat at the skull base.^{27, 36, 172} Furthermore, the presence of alanine, although not invariably present, is considered to be characteristic of meningiomas.^{27, 36, 38, 172}

Figure 11–3. Glioblastoma multiforme (GBM). Representative single-volume proton MR spectra of a histologically proven GBM using a STEAM sequence for the TE = 20 msec spectrum and a PRESS sequence for the TE = 270 msec spectrum and a TR = 1500 msec for both studies. Note the large lipid/lactate (Lip/Lac) peak between 0.4 and 1.8 ppm, which probably represents the necrotic core of the tumor, and the lower *myo*-inositol resonance, compared with the lower-grade brain tumors and the elevated choline peak intensity relative to creatine peak intensity for the GBMs.

Figure 11-4. Table of relative brain metabolite levels in brain tumors. The bar graph represents the average of the relative levels of *N*-acetylaspartate (NAA), choline (CHO), *myo*-inositol (MYO), and lipase/lactate (Lip/Lac) found in 10 histologically proven cases of low-grade glioma, high-grade glioma, and glioma multiforme. The relative values were determined by dividing the peak resonance area of each metabolite found in the tumor volume by the peak resonance area of Cr found in the tumor volume examined. Ratios were determined on single-volume MRS studies conducted at both a TE = 20 and a TE = 270 msec with a TR = 1500 msec.

Figure 11-5. Chemical shift imaging Planscan of tumor region. MRI is used to plan the multivolume 1D proton spectroscopic imaging study of a 49-year-old man with a histologically proven high-grade anaplastic astrocytoma located in the left temporal lobe.

Figure 11–6. Chemical shift imaging pretreatment of tumor. Multi-volume one-dimensional spectroscopic image (1D SI) of high-grade anaplastic astrocytoma located in the left frontotemporal lobe before treatment with a chemotherapy (BCNU) regimen. The patient did not respond to a complete course of radiation therapy and two courses of intra-arterial cisplatin. Volume elements are $1 \times 2 \times 3$ cm in size, and studies were performed using a 1D PRESS sequence, with TE = 272 msec and TR = 1600 msec. Note the presence of elevated choline resonances (3.2 ppm) in volumes 18 to 21.

Lac levels may be elevated in some meningiomas.^{27, 38} However, Castillo and colleagues have reported that in their experience meningiomas may be indistinguishable from astrocytomas on the basis of their proton MR spectra and only rarely display an identifiable alanine peak.³⁸ Although characteristic conventional MRI features usually allow confident diagnosis of these tumors (which are the most common adult extra-axial neoplasms), proton MRS is very helpful in atypical cases.

Metastases are another class of intracranial neoplasms that have been studied with proton MRS. Although they

usually do not pose much of a diagnostic challenge when they are multiple, based on conventional MRI, metastases can be problematic when they are solitary because it may be difficult to distinguish them from primary brain neoplasms.³⁶ Unfortunately, the proton MR spectra of intracranial metastases are often nonspecific and indistinguishable from those of primary brain tumors; using long TE PRESS technique, they display low NAA levels, low Cr levels, and elevated Cho levels.^{35, 36, 38, 129, 172}

Although in theory NAA should not be present in metastases because of their lack of neural or glial components, it

Figure 11-7. Chemical shift imaging of tumor after treatment. Multivolume one-dimensional spectroscopic image (1D SI) of high-grade anaplastic astrocytoma 3 months after completion of BCNU chemotherapy rounds. Note the marked decreases in choline resonances at 3.2 ppm in volumes 18 to 21. The patient was alive 5 years after treatment of his brain tumor.

frequently is present in proton MR spectra, presumably secondary to voxel contamination with adjacent brain parenchyma or due to the presence of *N*-acetylated metabolites on their cell membranes.³⁶ One study indicated that although no statistically significant difference existed between peak areas of Cho, Cr, and NAA in spectra of metastases and those of high-grade astrocytomas, a trend toward higher Cho/Cr and Cho/NAA ratios in astrocytomas did exist, and lipid and Lac peaks were more common in intracranial metastatic lesions³⁶ (Figs. 11-8 and 11-9). Another study

suggested that lipid peaks were often present in metastases, particularly those from breast carcinoma.^{38, 220}

Kinoshita and colleagues suggested that glycine levels may be used to distinguish metastatic tumors from glial tumors or neuroectodermal tumors; glycine levels were noted to be markedly elevated in GBMs, high-grade astrocytomas, an ependymoma, and a medulloblastoma, whereas they were low in metastatic tumors.^{115, 121}

One study has evaluated the MR spectrum of acoustic schwannomas, and absence of Cr, marked reduction in NAA, and increased lipids were noted.^{27, 36} Other MRS studies have attempted to distinguish astrocytomas from ependymomas and primitive neuroectodermal tumors (PNETs); these studies have demonstrated reduced NAA/Cho and elevated Lac/Cho ratios in astrocytomas and ependymomas in comparison with PNETs.^{200, 225, 226, 241, 252}

One report described MRS findings in gliomatosis cerebri; these cases all demonstrated elevated Cho/Cr and Cho/NAA levels as well as varying degrees of decreased NAA/Cr ratios.¹⁵ This study demonstrated a maximum Cho/NAA ratio of 1:3 in low-grade lesions, compared with 2.5 for anaplastic tumors; in addition, Lac peaks were noted in grade III and IV lesions.¹⁵

MRS may be able not only to facilitate diagnosis and accurate classification of de novo brain tumors but also to allow differentiation of recurrent tumor and tumor progression from radiation necrosis, post-treatment effects, or edema.^{21, 36, 38, 200} Thus, MRS may be useful in evaluating the response to therapy in patients with brain tumors. Radiation necrosis occurs from approximately 6 to 24 months after completion of therapy, is seen more commonly with high-grade astrocytomas, and may be indistinguishable from recurrent tumor by conventional gadolinium-enhanced MRI.³⁸ Elevated Lac levels are seen in proton MR spectra of patients who have received 40 Gy or more of radiation to the brain, even when the conventional MRI study does not yet demonstrate any structural abnormality within the resection bed.³⁸

One study involving 25 patients with cerebral astrocytomas who received a combination of radiation and chemotherapy demonstrated increased Cho/NAA and Cho/Cr ratios as well as the presence of Lac, in cases of recurrent tumor, compared to markedly decreased levels of NAA, Cho, and Cr and the presence of a broad intense peak between 0 and 2.0 ppm in cases of radiation necrosis.^{38, 67} This broad peak, between 0 and 2.0 ppm, consists of free fatty acids, Lac, and amino acids.^{38, 67} However, because most therapy-induced tissue damage occurs in combination with areas of viable tumor, single-voxel techniques are not optimal for evaluation of these patients; 3D MR spectroscopic imaging (MRSI) is preferable for distinguishing among areas of residual or recurrent tumor, radiation necrosis, and viable normal brain tissue.³⁶ Sensitivity and specificity of proton MRS for the detection of residual/recurrent tumor in radiated patients in one series were 71% and 100%, respectively, and serial MRS in the same series allowed differentiation of necrosis and tumor progression; progressive decreases in Cho levels and mild increases in NAA levels correlated well with therapy success.^{36, 231}

Other groups have reported similar success in distinguishing radiation necrosis from recurrent tumor with proton MRS, although a few have reported contradictory re-

Figure 11-8. Metastatic lung carcinoma (CA). A single-volume brain proton MR spectrum was obtained using a TE = 20 msec in a 70-year-old patient presumed to have metastatic lung carcinoma. The definitive diagnosis was primary lung carcinoma.

sults; the reasons for differences in results may include the fact that Cho levels may be elevated in early radiation-induced lesions because of demyelination and reactive astrocytosis.^{44, 49, 56, 74, 113, 200} In addition, Bizzi and coworkers reported that MRS is useful in the surveillance of lym-

phoma following treatment.^{19, 36} Furthermore, Tedeschi and coauthors demonstrated that interval changes in Cho levels during long-term (3.5 years) follow-up with MRS allow differentiation of stable from progressive varieties of glioma.^{21, 235} A recent study by Henry and associates suggested

Figure 11-9. Metastatic lung carcinoma (CA). A single-volume brain proton MR spectrum was obtained using a TE = 270 msec in a 70-year-old patient with a presumed metastatic lung carcinoma.

that MRS and MR perfusion imaging (relative cerebral blood volume mapping) may be complementary modalities that, when combined, may be able to noninvasively differentiate tumor from necrosis, post-treatment effects, or edema in patients with treated gliomas better than either modality alone.⁹⁴

Another application of proton MRS is the differentiation of gliomas from hamartomas, particularly in the setting of phakomatoses such as neurofibromatosis, type I.²⁰⁰ NAA/Cho, NAA/Cr, and Cr/Cho ratios in hamartomas are closer to those of normal brain tissue than to those of gliomas; specifically, studies have demonstrated Cho/Cr ratios greater than 2.0 in gliomas, between 1.3 and 2.0 in hamartomas, and less than 1.3 in normal brain tissue.^{33, 81, 200}

Therefore, a multitude of applications of proton MRS exist in the field of brain tumor diagnosis and management, and MRS is clearly playing an increasingly valuable clinical role that complements the roles of conventional structural MRI and other physiologic imaging modalities such as PET.

Epilepsy

Proton MRS has a major clinical application in the localization of subtle epileptogenic foci that are not evident on conventional structural MRI sequences as well as in the prognostication and planning of epilepsy surgery. Specifically, single-voxel MRS may confirm a structurally abnormal epileptogenic focus, whereas MRSI may detect foci that appear normal on conventional structural MR images but demonstrate definite metabolic abnormalities, such as those associated with very subtle malformations of cortical development.^{54, 169} In fact, one study suggested that the sensitivity of MRS for the detection of subtle neuronal

dysfunction was greater than that of PET.^{2, 200} The advent of viable surgical approaches to the management of epilepsy, as well as the potential for future less invasive treatment modalities such as Gamma knife radiosurgery, has made precise localization of seizure foci critical.¹⁶⁹

Most of the applications of MRS in epilepsy have been involved with temporal lobe epilepsy (TLE), the most common type of partial epilepsy, and many cases have been refractory to medical therapy.²¹ The most common lesion associated with TLE is mesial temporal sclerosis (also called hippocampal sclerosis), noted in approximately 65% of cases of TLE.^{9, 21, 54} Although in classic cases of mesial temporal sclerosis (MTS) the involved hippocampus is easily identified by a combination of volume loss and signal hyperintensity on T2-weighted and fluid-attenuated inversion recovery (FLAIR) sequences, 20% of patients with TLE have normal structural MRI scans and the findings in children generally tend to be more subtle than those in adults.^{169, 200} NAA, NAA/Cho, NAA/Cr, and NAA/(Cho + Cr) all are decreased in atrophic hippocampi, as well as in nonatrophic hippocampi with abnormal electroencephalographic (EEG) findings, according to the results from the series by Ende and coworkers^{21, 68} (Figs. 11-10 and 11-11).

In addition, even when seizure onset and structural MRI abnormalities are clearly unilateral, MRS has shown that bilateral temporal lobe abnormalities are present; bilateral metabolic abnormalities are found in approximately 40% to 50% of TLE cases, and in such cases these abnormalities appear to be more diffuse than the corresponding structural abnormalities would suggest.^{53, 54, 58, 68, 95, 170}

Kuzniecky and colleagues also argued that the lack of correlation between structural hippocampal volume loss and proton MRSI metabolic abnormalities reflects the presence of distinct pathophysiologic processes that are coexistent in cases of MTS.¹³¹ Gadian's investigators, examining

Figure 11-10. Study of temporal lobe epilepsy (TLE), right anterior hippocampal volume. Oblique spectroscopic imaging (SI) study of the hippocampus of a 28-year-old patient with TLE. This volume represents the peak resonance area of the metabolites of the normal right hippocampus. A TE = 135 msec and a TR = 1500 msec were used. The SI study used an angled SI region of interest of 25 degrees, which was parallel to and covered both the left and right hippocampal regions. Each volume element was 1 × 1 × 1.5 cm in dimensions.

Figure 11-11. Study of temporal lobe epilepsy (TLE), left anterior hippocampal volume. Oblique spectroscopic imaging (SI) study of the hippocampus of a 28-year-old patient with TLE. This left anterior SI volume of the hippocampus was found to have an approximately 40% decrease in *N*-acetylaspartate (NAA) peak resonance area compared to the volume examined on the contralateral right hippocampus and coincided with the electroencephalographic findings indicating a left temporal lobe seizure focus.

a mixed group of patients with partial seizures, mostly with TLE, reported a 9% decrease in the NAA content of the epileptogenic temporal lobe, with an increase of 14% and 17%, respectively, in the levels of Cr and Cho.^{75, 120}

Additional multivoxel MRS studies have shown not only reduced NAA levels in the diseased hippocampus but also the presence of Lac peaks in the spectra of epileptogenic foci when studied within 6 hours of seizure activity.^{41, 50, 170, 200, 223} The postictal Lac peak has been described as having potential lateralizing value, since only one side demonstrates a peak in Lac, even in patients with bilateral disease.^{50, 223}

Cendes and associates noted that correct lateralization of the seizure focus in patients with TLE was possible in 83% of cases in their large series with MR volumetry and 86% with MRSI.^{42, 120} Ende and coauthors found that the NAA/(Cho + Cr) ratio was the most sensitive measure for lateralization compared with ictal EEG^{68, 120}; they also noted that in unilateral TLE, the reduced levels of NAA in the hippocampus contralateral to the atrophic one predicted poor clinical outcome following surgical resection of the epileptic focus.^{21, 68} Thus, MRS may provide important prognostic as well as diagnostic information.

MRS has also shown promise in the evaluation of patients with extratemporal epilepsy, including those with neocortical epilepsy. This class includes the second largest group of patients with complex partial seizures refractory to medical therapy—those with frontal lobe epilepsy.¹

Garcia and coworkers⁷⁶ reported that, in a series of eight patients with frontal lobe epilepsy, the mean NAA/Cr ratio in the epileptogenic frontal lobe was decreased by 27%, compared with that of the contralateral frontal lobe, with decreases of at least 5% in each individual.¹ In addition, in patients with structural MR evidence of malformations of cortical development (MCD) or neuronal migration disorders (NMD), MRS provides insight into both the pathophysiology and true spatial extent of the disease processes.

Li and coworkers¹³⁷ showed that the maximal NAA/Cr

ratio decrease, indicative of metabolic dysfunction, localized to the structural malformation noted on conventional MRI in 23 cases of MCD (including focal cortical dysplasia, heterotopia, polymicrogyria, and tuberous sclerosis); however, less impressive decreases also extended to normal-appearing areas of brain tissue adjacent to the structural lesion.

Simone and colleagues,²²² in their series of 15 patients with NMD, noted abnormally decreased NAA/Cr and Cho/Cr ratios in these lesions when compared with gray and white matter of neurologic controls; they also noted abnormally decreased Cho/Cr ratios in the normal-appearing brain contralateral to the identified NMD, when compared with gray and white matter of neurologic controls. The absence of correlation between the NAA/Cr decrease, EEG abnormalities, and NMD lateralization suggested that the metabolic abnormality may be related more to the underlying structural and functional alterations within the focus of NMD than to actual epileptic activity in the lesions, and that the Cho/Cr ratio decreases may reflect more extensive diffuse hypomyelination than what the structural MRI had suggested.²²²

Alzheimer's Disease

Alzheimer's disease is the most common form of dementia in older adults and represents approximately 40% to 60% of all such dementias.^{21, 38} The disease is characterized by decreased cortical acetylcholine, neuronal loss, amyloid deposits, and neurofibrillary tangles. Diagnosis, which may be difficult, is based primarily on clinical criteria, and imaging has been used primarily for excluding other possible causes of dementia, such as intracranial mass lesions and subcortical vascular disease. Nevertheless, structural MRI can confirm clinical findings in Alzheimer's disease by demonstrating preferential atrophy of the hippocampi and temporoparietal cortices. MRS, however, may enable earlier diagnosis of this disease.

The proton MR spectrum in Alzheimer's disease demonstrates an abnormally elevated MI/Cr ratio and an abnormally decreased NAA/Cr ratio.^{156, 158, 159, 197, 217} This combination of spectroscopic findings distinguishes Alzheimer's disease from normal conditions in the elderly, whereas the elevated MI/Cr ratio distinguishes Alzheimer's disease from other dementias, with the possible exception of Pick's disease.¹⁹⁷

Reduced levels of NAA are noted in the frontoparietal regions and temporal lobes, including the hippocampi.^{21, 209, 234} In Pick's disease, however, decreased NAA levels and elevated MI levels are noted in the frontal lobes, and no such similar metabolic abnormalities are present in these brain regions in those with Alzheimer's disease; thus, the differentiation between Alzheimer's disease and Pick's disease was made correctly on the basis of proton MRS findings in 92% of cases in one series.^{21, 69} However, many confounding metabolic disorders can also result in abnormal MI/Cr ratios: renal failure, diabetes mellitus, chronic hypoxic encephalopathy, and hypernatremia can all result in elevated MI concentrations, whereas hepatic encephalopathy and hyponatremia can result in decreased MI concentrations.^{124-126, 135, 154, 197, 249}

Degenerative and Metabolic Brain Disorders

Various brain metabolic disorders, including primary leukodystrophies and mitochondrial disorders, have been studied with proton MRS. Although the MR spectral findings, conventional imaging findings, and clinical symptoms of most of these degenerative brain disorders (many of which present in childhood) are nonspecific, MRS can sometimes be useful in distinguishing the various clinical entities.

Wang and Zimmerman²⁵⁵ have divided brain metabolic disorders into five general categories:

1. Disorders of lipid metabolism.
2. Disorders of carbohydrate metabolism and respiratory chain.
3. Disorders of amino acid metabolism and the urea cycle.
4. Primary white matter disorders.
5. Miscellaneous metabolic disorder not fitting into the previously described categories.

Furthermore, peroxisomal and mitochondrial disorders may be considered to be subcategories of these five categories.²⁵⁵

Disorders of lipid metabolism include the following²⁵⁵:

1. Abnormalities of long-chain fatty acid metabolism (peroxisomal diseases), such as Zellweger's syndrome (in which peroxisomes are deficient or absent).
2. Rhizomelic chondrodysplasia punctata (in which several peroxisomal enzymes are absent).
3. Adrenoleukodystrophy (in which a single peroxisomal enzyme is deficient).

Adrenoleukodystrophy is unique, in that among hereditary leukodystrophies it is the only one associated with an increased Cho signal at times other than during the early stage of acute demyelination.²¹ In childhood adrenoleuko-

dystrophy, decreased NAA/Cr and increased Cho/Cr ratios are present in addition to elevated Lac, Glu, Gln, and MI peaks.^{38, 240} The decline in the NAA/Cr ratio in X-linked adrenoleukodystrophy both parallels disease progression and can predate emergence of white matter hyperintensities on conventional T2-weighted MRI scans.^{51, 214}

Disorders of carbohydrate metabolism include diabetes mellitus and galactosemia. In diabetes mellitus, MR spectra reveal elevated glucose signal and an acetone peak at 2.2 ppm owing to hyperglycemia and ketogenesis.¹⁹⁴ In addition, it is suggested that the extent of brain injury in severe diabetic ketoacidosis may be evaluated with MRS because elevated Lac levels have been noted in individuals eventually dying of cerebral herniation and cardiac arrest.²⁵⁵ Furthermore, in galactosemia, a condition in which one of various inborn errors of metabolism prevents normal conversion of galactose to glucose, neonates demonstrate elevated brain galactitol peaks in proton MR spectra at 3.67 and 3.74 ppm at the time of symptom onset; this corresponds to elevated levels of galactitol in brain autopsy specimens in fatal cases.^{254, 257}

Disorders of the respiratory chain include mitochondrial disorders such as mitochondrial myopathy, encephalopathy, lactic acidosis, and strokes (MELAS) and myoclonic epilepsy with ragged red fibers (MERRF), Kearns-Sayre syndrome, and pyruvate dehydrogenase deficiency (PDD). MRS may provide useful information regarding the extent of metabolic derangement, severity of disease, and response to therapy.^{64, 92, 119, 255} All of these diseases are characterized by brain Lac accumulation secondary to impaired mitochondrial oxidative phosphorylation.²⁵⁵ Figure 11-12 illustrates an example of a MELAS spectrum.

MRSI is the preferred approach of evaluating distributions of cerebral metabolites in these disorders, since the distribution of Lac in the brain may vary significantly across different anatomic regions and since metabolic abnormalities may be present even when no corresponding conventional brain MRI abnormalities are present.^{34, 146} The most striking Lac elevations are noted in regions of brain displaying the most marked structural abnormalities on conventional MR studies. The peaks have been noted in the parieto-occipital gray and white matter in MELAS; occipital cortex in MERRF; brain stem, basal ganglia, and occipital cortex in Leigh's syndrome; and cortical gray matter in Kearns-Sayre syndrome.²⁰⁰ All of these syndromes are also associated with decreased NAA/Cr ratios, presumably related to neuronal loss or dysfunction.^{89, 146} However, PDD has been associated more marked reductions in NAA/Cr ratios in addition to elevated Lac levels and decreased Cho/Cr ratios; in fact, Zimmerman and Wang have noted one case in which NAA was completely absent from the spectrum.^{214, 255, 262}

Disorders of amino acid metabolism include entities such as phenylketonuria (PKU), the most prevalent of this class of disorders, and maple syrup urine disease (MSUD).

PKU results from a deficiency of the hepatic enzyme phenylalanine hydroxylase and demonstrates an autosomal recessive mode of inheritance.²¹⁰ In patients with PKU, the proton MR spectrum is remarkable only for an abnormal elevation of the phenylalanine signal at 7.3 ppm, which is a finding that is specific for this disease.²⁵⁵

In patients with MSUD, long TE proton MR spectra

Figure 11-12. Mitochondrial encephalomyopathy-lactic acidosis-and stroke-like symptoms syndrome (MELAS) in a 16-year-old patient. Single-volume proton MRS study ($2 \times 2 \times 2$ cm) over the basal ganglia. A TE of 135 msec was used to determine the presence of an inverted peak at 1.3 ppm. Both the left and right basal ganglia area showed the presence of an inverted lactate peak, centered at 1.3 ppm.

reveal a peak at 0.9 to 1.0 ppm in addition to a reversible decrease in the NAA/Cr ratio during acute metabolic decompensation.^{71, 253, 255} Abnormal accumulation of valine, leucine, and isoleucine occurs in the CSF, blood, and tissues as a consequence of defective oxidative decarboxylation.^{65, 255}

Ornithine transcarbamylase deficiency is the most common disorder of the urea cycle and is inherited in an X-linked dominant fashion. In patients with this condition, hyperammonemia and intracerebral glutamine accumulation lead to cerebral edema, neuronal loss, and white matter gliosis.^{122, 255} Reported MR spectral abnormalities include elevated glutamine levels in a case of hyperammonemia and decreased MI with a normal glutamine level in one patient with a normal serum ammonia level.^{52, 194}

The primary white matter disorders include Canavan's disease, Alexander's disease, and Pelizaeus-Merzbacher disease, among others. In patients with Canavan's disease, which is the only primary white matter disorder with truly specific findings on MRS, markedly increased NAA levels have been noted, probably secondary to impaired NAA breakdown related to a deficiency in the enzyme aspartoacylase^{21, 38, 89, 143} (Fig. 11-13). Canavan's disease is the only metabolic disorder that is associated with an elevated NAA level.^{253, 255, 259} Other findings in Canavan's disease include elevated MI levels and decreased Cho and Cr peaks; the decreased Cho is probably due to failure of myelination, whereas a decreased Cr level may reflect spongy degeneration.²⁵⁵

In patients with Alexander's disease, decreased NAA levels and elevated Lac levels are observed, most prominently in the frontal lobe; the structural white matter abnormality extends from the frontal lobes posteriorly.^{89, 255}

Pelizaeus-Merzbacher disease may be characterized by normal spectra or slight decreases in NAA in the basal ganglia in the early stages and by more prominent NAA decreases and Cho increases in advanced disease.^{89, 133, 228}

Several as-yet unclassified primary white matter diseases have also been reported. For example, van der Knaap and coauthors²⁴⁸ have reported a new leukoencephalopathy in nine children manifested by severe white matter degeneration with elevated Lac and Glu and virtual disappearance of most other metabolites in MR spectra.²⁵⁵ In addition, the studies of Tedeschi and associates^{21, 233} have described a new white matter syndrome resulting from a metabolic defect producing hypomyelination and secondary axonal dysfunction characterized by a prominent decrease in NAA, Cho, and Cr levels and an increase in Lac.

In general, childhood demyelinating disorders and neuronal degenerative disorders typically demonstrate decreased NAA/Cr ratios, with the degree of decrease corresponding to the extent of white matter disease and degree of cortical atrophy, respectively, depicted on conventional MR images.^{38, 246} Decreased NAA levels and elevated Lac levels are noted in Schilder's and Cockayne's diseases in addition to the disorders described earlier.^{38, 89}

Still other metabolic disorders are characterized by specific pathologic changes in proton MR spectra. For example, abnormal lipid peaks are seen in Niemann-Pick disease type C (a lysosomal disorder), low Cr levels are present in guanidinoacetate methyltransferase deficiency, and elevated Gly levels are present in nonketotic hyperglycinemia.¹⁹⁹ Furthermore, in adult hepatic encephalopathy, increased levels of Glu and decreased levels of MI and Cho in proton MR spectra have been described; the Glu elevation is thought to be secondary to hyperammonemia.^{196, 255} MRS

Figure 11-13. Canavan's disease. A single-volume proton, TE = 270 msec MRS study of a 4-month-old baby with a diagnosis of Canavan's disease. Note the level of *N*-acetylaspartate (NAA), which was found to be three times higher than that found in the normal frontal lobe of age-matched infants using TE = 20 msec STEAM proton MR spectrum of Canavan's disease. (See Wang ZJ, Zimmerman RA: Proton MR spectroscopy of pediatric brain metabolic disorders. *Neuroimaging Clin North Am* 8:781-807. 1998.)

may even be able to detect subclinical encephalopathy, since the reduction in MI level may occur even in patients with hepatic disease without neurologic symptoms.^{38, 126, 195} The specificity of these abnormalities may be useful in both diagnosis and monitoring of therapeutic efficacy in these conditions.

Stroke

Stroke is another clinical condition in which MRS has been applied. Although the utility of MRS in the acute stroke setting may be less than that of diffusion and perfusion MRI, or even noncontrast CT, since a critical need for rapid imaging exists in the hyperacute and acute setting for decision making regarding need for thrombolysis, MRS may be very useful in the chronic phase and for monitoring recovery from stroke.^{169, 175}

The first detectable change in the MR spectrum that occurs following the onset of cerebral ischemia is the appearance of the Lac doublet.¹⁸⁹ The Lac peak has been noted within minutes of induction of ischemia in animal models, and its level tends to rise over the first few hours after onset.^{3, 160, 165, 189} A blood flow threshold of 20 mL/100 g of brain tissue per minute has been described in animal models for the appearance of Lac, but whether a similar threshold exists for humans is not certain.⁵⁷

Studies in humans have also noted the presence of Lac during the first few days following symptom onset, correlated with ischemia and resultant edema^{169, 256} (Fig. 11-14). Not only does MRS demonstrate spectral changes before comparable changes in signal intensity of ischemic tissue on conventional T2-weighted MR images occur, but also the extent of cerebral tissue displaying metabolic abnormalities exceeds the extent of signal hyperintensity on the T2-weighted images.^{10, 80, 160, 165, 189} In addition, the con-

centration of Lac in ischemic tissue is not homogeneous; rather, the center of the infarct tends to demonstrate higher concentrations than the infarct periphery.⁷⁷ Concentrations of Lac during the evolution of an infarct also demonstrate temporal as well as spatial variability.^{84, 189} Although the presence of Lac signifies ischemia, it does not necessarily signify actual irreversible infarction.^{10, 17, 80, 189}

A later and more specific spectral change signifying actual cerebral infarction that occurs during the evolution of a clinical stroke is a reduced NAA concentration.¹⁸⁹ Several studies have demonstrated both a reduction in NAA and appearance of Lac in human stroke.^{10, 86, 207, 256} The reduced NAA level is thought to be related to actual neuronal damage (neuronal cell death or replacement by non-NAA-containing cells, such as glial cells, which occurs in a delayed fashion relative to the changes seen in Lac levels) and is correlated highly with clinical outcome.^{165, 166, 169, 189}

Pereira and coworkers studied a series of 31 patients with new middle cerebral artery distribution infarcts within the first 72 hours following clinical onset of stroke symptoms with proton MRS and T2-weighted structural MRI. The authors noted that the combination of infarct volume and NAA concentration could accurately predict clinical outcome.¹⁷⁸

Decreases in NAA levels can often be identified in initial MR spectra; in fact, one study using an animal model demonstrated NAA reduction within 30 to 60 minutes following induction of cerebral infarction.^{96, 174, 189} Regional variability in NAA concentrations is noted, just as with Lac, and the areas demonstrating the greatest elevation of Lac within an infarct also demonstrate the most marked NAA depression.^{10, 70, 84, 189}

Changes in Cho and Cr concentrations during acute infarction are more variable than changes involving Lac and NAA. Many studies have reported decreases in Cr levels.^{28, 70, 72, 77, 85, 207} Nevertheless, a few studies docu-

Figure 11-14. Hypoxic event/mitochondrial disorder in a 13-year-old patient. A single-volume, TE = 135 msec PRESS proton MRS study showed the presence of an inverted lactate peak in the basal ganglia. Lactate was found in both the left and right basal ganglia areas and also in various areas of the left and right frontal lobes.

mented no consistent change in Cr levels,^{72, 77, 84, 207} and two studies have even noted increased levels of Cr.^{10, 80}

Variability in Cho levels has been equally problematic. Elevated Cho levels have been reported in acute infarction, and this elevation may be related to ischemic demyelination.^{10, 80, 189} However, this finding is not consistent, since several studies have noted decreased^{28, 84} or unchanged^{72, 77, 207} Cho levels.

In the subacute stage, Lac levels decrease progressively from the peak levels that are present in the acute stage with an approximately 36% reduction in Lac levels noted per week.⁸⁵ Lac may disappear or persist in low levels in the chronic stage; it may also disappear in the subacute stage and recur in the chronic stage.^{10, 78, 84, 85, 100, 204} The reasons for the persistence of Lac peaks into the subacute and chronic phases are not entirely clear.¹⁸⁹

In the chronic stage, NAA, Cr, and Cho levels all decrease.^{189, 207} Specifically, the NAA level decreases in an irreversible fashion at an average rate of approximately 29% per week.^{10, 70, 77, 85, 100} The rate of decrease of Cr and Cho is less than that of NAA, although these levels also decrease in the subacute and chronic phases.^{66, 70, 77, 189} The smaller relative decrease of Cho and Cr is probably related to both the relatively decreased vulnerability of glial cells to ischemia compared to neurons and the reactive gliosis that occurs as a result of ischemic brain injury.^{85, 189}

Hypoxic-Ischemic Injury

MRS has been used to evaluate brain damage due to perinatal asphyxia, or hypoxic-ischemic injury (HIE).^{11, 87, 90, 208} HIE is the main cause of developmental injury that leads to cerebral palsy. In many cases, the most severe

damage (selective neuronal necrosis) involves the occipital gray matter and is manifested as a reduction in NAA and Cr levels and a proportional increase in Cho levels.²⁰⁸ This suggests that significant astrocyte survival may be present in these cases of neuronal necrosis secondary to HIE.²⁰⁸

In particularly severe cases, a Lac peak may also be present, with the Lac peak appearing during the first 24 hours and persisting for at least 48 hours.¹⁷⁷ This finding often precedes the reduction in the NAA/Cr ratio and the increase in the Cho/Cr ratio, both of which have been noted on MRS studies performed 1 to 2 weeks after the initial insult.²¹⁴ The severity of the MRS changes appears to be well correlated with the severity of the initial insult and the clinical outcome; persistent NAA and Cho peak abnormalities and the presence of Lac are associated with poor prognosis.^{13, 90, 97, 208, 218} Specifically, the presence of Lac in the acute phase has been associated with poor neurocognitive status at 1 year of age.¹³ Barkovich and coauthors¹³ have demonstrated that Lac/Cho ratios in the basal nuclei had particularly highly statistically significant associations with clinical outcome.

The distribution of Lac elevation in the brain also correlates well with the severity of the injury; in severe asphyxia, the basal ganglia demonstrate greater Lac elevation than the arterial watershed regions; in mild to moderate asphyxia, the watershed regions demonstrate greater Lac elevation.¹⁴ Penrice and colleagues have shown that Lac/NAA ratios in the thalami, in particular, correlate highly with degree of severity of asphyxia; the ratios in normal infants were less than 0.3, the ratios in infants with asphyxia were greater than 0.4, and the ratios in severely affected infants were greater than 0.5.^{14, 176}

Finally, Pu and others have shown that cases of moderate to severe HIE display detectable brain glutamate/gluta-

mine (Glx) peaks on proton MR spectra.¹⁸⁴ Elevated Glx/(Cr + PCr) ratios in these cases correlated positively with the Sarnat stage of HIE on both initial and follow-up MRS studies.¹⁸⁴

Cerebral Infections

Most of the applications of proton MRS in evaluation of intracranial infections have involved the study of acquired immunodeficiency syndrome (AIDS) and AIDS-related conditions. Nevertheless, evaluation of cerebral abscesses with MRS has been documented.

Cerebral abscesses can be differentiated from necrotic brain neoplasms by MRS. Grand and coworkers, in their series of 34 cystic intracranial lesions, showed that at a TE of 136 msec, the detection of an amino acid resonance at 0.9 ppm in bacterial abscesses allows differentiation from necrotic neoplasms, which do not demonstrate this spectral peak.⁸⁸ MR spectra of brain abscesses demonstrate absent or low Cho and Cr levels and a relatively decreased level of NAA as well as the possible presence of substantial amounts of Lac.^{38, 188} MR spectra of abscesses may show other peaks at 0.97, 1.24, 1.36, 1.50, 1.89, 2.02, and 2.14 ppm, and the exact significance of these additional peaks is not known.³⁸

Various studies have shown resonances from acetate, succinate, and some amino acids (peaks not seen in brain neoplasms), in addition to Lac, Ala, and lipid peaks (which may also be seen with certain brain tumors).³⁹ Similar findings have been reported by Castillo and colleagues and others in cases of toxoplasmosis and cysticercosis^{38, 39} (Figs. 11-15 and 11-16).

The few reports in the literature regarding MR spectra of other infectious processes include studies of intracranial

tuberculomas, Creutzfeldt-Jakob disease, and herpes simplex encephalitis.³⁹ Prominent lipid resonances have been noted in intracranial tuberculomas, with particularly important peaks at the 1.3 and 0.9 ppm, corresponding to the methylene and terminal methyl groups of fatty acids, respectively.³⁹ Abnormally decreased NAA levels in both white matter and gray matter, as well as abnormally increased levels of MI in the white matter, have been noted in Creutzfeldt-Jakob disease, whereas reductions in the NAA/Cho and NAA/Cr ratios and the presence of Lac peaks have been noted in herpes encephalitis³⁹ (Figs. 11-17 and 11-18).

Acquired immunodeficiency Syndrome

Various studies of applications of MRS to the evaluation of metabolic disturbances related to HIV infection have been recently performed; these studies have demonstrated reduced NAA concentrations in HIV-positive patients,^{45-48, 112, 155, 203, 227, 239} including those who are asymptomatic¹⁵¹ or who display normal structural MRI findings.²³⁹ Increases in Cho and progressive decreases in NAA levels have been noted with disease progression^{45-48, 112, 155, 169, 203, 227, 239}

Increased levels of glutamine and MI have been noted in the late stages of HIV dementia.⁴⁶ One study reported a decrease of both NAA and Cr along with increases in Cho and MI both in structural brain lesions and in normal-appearing areas of brain (on conventional MRI) in patients with AIDS.^{21, 149} It is not clear whether the metabolic abnormalities in AIDS are due directly to the virus or whether they represent secondary effects related to opportunistic infection or AIDS-related neoplasms.²¹ Nevertheless, it appears that MRS may be able to detect subclinical metabolic abnormalities prior to clinical and brain struc-

Figure 11-15. Toxoplasmosis. This was a single-volume STEAM MRS study (TE = 20 msec) of a 50-year-old patient with human immunodeficiency virus (HIV) infection with proven toxoplasmosis. Note the large decrease in metabolites and the presence of a large lipid or cellular breakdown peak between 0.5 and 1.8 ppm.

Figure 11-16. Proven toxoplasmosis in a 50-year-old patient with human immunodeficiency virus (HIV) infection. The MRS study used a TE = 270 msec PRESS. Again, note the decreased levels of brain metabolites and the presence of lipids and cellular breakdown peaks. Note the relationship between the choline and creatine peak in toxoplasmosis versus viral encephalitis. Normally, these peak ratios (TE = 270 msec, between 1.2 and 1.4) in patients with toxoplasmosis are much less than those observed in the active viral inflammatory processes. (Normally, choline-to-creatine peak area ratios using a TE = 270 msec are greater than 1.5 in viral inflammatory processes.)

tural manifestations of the disease.¹⁹⁹ The diffuse cortical atrophic changes and white matter hyperintensities noted on T2-weighted images are late findings in the AIDS dementia complex.

MRS may be particularly useful in the evaluation of infants of HIV-infected mothers; it may be able to demonstrate abnormalities in the infant brain as early as 10 days after birth, whereas seroconversion is difficult to determine during the first 6 months and conventional brain MR images may be normal.^{38, 55}

MRS may also prove to be a useful means of monitoring both disease progression and treatment effects in patients

with AIDS.^{48, 169, 203} Specifically, it has been suggested that monitoring of the efficacy of antiretroviral therapy—and even prediction of a patient's response to therapy—may be performed with MRS.^{199, 258}

Multiple Sclerosis

Multiple sclerosis (MS) is a disease that is manifested primarily as multifocal demyelination, although significant axonal injury and wallerian degeneration are usually present as well.^{7, 109, 145, 169, 199} In fact, the axonal loss, rather than

Figure 11-17. Herpes simplex viral (HSV) encephalitis in a 55-year-old patient. A 3 × 4 × 3 cm volume was used. The MRS study used a STEAM TE = 20 msec sequence. a.a., amino acids.

Figure 11-18. Active case of herpes simplex viral (HSV) encephalitis in a 55-year-old patient. This was a PRESS MRS study (TE = 270 msec).

the demyelination, may be responsible for the neurologic impairment seen in patients with MS.^{147, 199}

Active demyelinating plaques generally demonstrate enhancement on gadolinium-enhanced MR scans in addition to displaying hyperintensity on T2-weighted and FLAIR conventional MR sequences.³⁸ Substantial reductions in NAA concentration are noted in acute (active) MS lesions, and these reductions correlate highly with clinical neurologic impairment; partial recovery of NAA levels is also not uncommon, and these changes are also reflected in clinical improvement.¹⁹⁹ Whether the partial recovery of NAA levels is due to reduction of edema or to actual recovery of neuronal function is not clear.^{33, 199}

In the acute phase, marked increases in Cho concentration, moderate increases in Lac, and increases in mobile lipid peaks and "marker peaks" in the range of 2.0 to 2.6 ppm may be present.^{7, 21, 91} The increase in Cho levels is due to release of phosphocholine and glycerophosphocholine during active demyelination.²¹ The mobile lipid peaks are products of myelin breakdown, and the "marker peaks" are of uncertain etiology but appear to be typical of demyelinating conditions in general.^{21, 38} One study even suggested that lipid concentration increases may precede signal hyperintensity development on T2-weighted conventional MR sequences.^{167, 199}

The presence of Lac may be related to local inflamma-

Figure 11-19. Active multiple sclerosis (MS) plaque. A single-volume proton STEAM MR study used a TE of 20 msec and a TR of 1500 msec in a patient with MS. The 2 × 2 × 2 cm volume was centered over the gadolinium-enhancing lesion located in the left cerebellum. Note the level of *myo*-inositol and other sugars (3.5 to 3.8 ppm) in the active plaque volume compared to the level in a non-gadolinium-enhancing inactive MS lesion.

Figure 11-20. Active multiple sclerosis (MS). This was a single-volume proton PRESS MRS study (TE = 270 msec) of a patient with a gadolinium-enhancing MS lesion.

tory infiltrates associated with the demyelinating plaques and their effects on local cerebral vasculature.^{7, 199}

A transient but significant decrease in Cr levels in the hyperacute stage may revert to normal in the subacute and chronic stages.¹⁹⁹

Increases in MI concentrations may be seen on short TE spectra; MI is usually detected when the demyelinating process is severe^{21, 61, 199} (Figs. 11-19 and 11-20).

Reduction of NAA/Cr ratios has been noted not only in structural lesions (visible demyelinating plaques) but even in white matter, which appears normal by conventional T2-weighted MRI; thus, these MRS findings suggest that conventional MR sequences may underestimate the true extent of brain tissue involvement by MS.^{21, 62, 73, 196} Although much of the reduction has been attributed to decreases in absolute concentrations of NAA, controversy exists regarding possible increases in Cr levels as well.^{62, 169, 192} Actually, the metabolite changes noted in MRS may be better correlated with actual clinical status than the number or volume of hyperintense structural brain lesions on conventional T2-weighted sequences.^{5, 210, 238} In fact, the reduction in NAA in the normal-appearing white matter correlates best with the degree of clinical disability.¹⁹⁹ Furthermore, preliminary data suggest that MRS may be used to monitor responses to therapy in patients with MS.^{169, 209} Gonen and colleagues⁸² have suggested that measurement of whole brain NAA concentration may serve as an effective and reproducible measure of disease load in MS and may be used to measure disease progression.

In the chronic phase of MS, axonal loss and mild cortical atrophy may occur. Although acute plaques demonstrate edema and demyelination, chronic plaques demonstrate gliosis and mild associated neuronal loss.²¹

Incomplete recovery of axonal damage leads to irreversible clinical disabilities. NAA levels are decreased in both

the structural lesions identified on conventional MR sequences and in surrounding normal-appearing white matter in the chronic phase, and this NAA decrease corresponds to the axonal and mild neuronal loss.¹⁹⁹ In addition, the fact that NAA levels may be normal in the acute phase of MS suggests that the axons in these cerebral regions have not yet sustained permanent damage, whereas in the chronic phase, when axonal loss has occurred, NAA levels are decreased.³⁸ Free mobile lipids and "marker peaks" may also be seen in MR spectra in the chronic phase in MS.³⁸

Because MRS provides valuable insight into the various stages of the evolution of MS plaques and the physiologic and metabolic changes associated with this evolution, in the near future it may also provide a reliable means of effectively monitoring responses to new therapeutic interventions. A recent study has already explored serial spectroscopic changes in active MS plaques during pharmacologic intervention.¹⁴² These interventions may be designed to target particular stages in the development and maturation of these plaques and thus may prevent progression of the disease.

Other Applications of Proton Magnetic Resonance Spectroscopy in the Central Nervous System

Other CNS applications of proton MRS include the study of psychiatric diseases, upper motor neuron disease (e.g., amyotrophic lateral sclerosis [ALS]), Huntington's disease, and parkinsonian syndromes, among other clinical entities.

In patients with schizophrenia, the most consistent findings include decreased NAA levels in the temporal lobes.¹¹⁶

In bipolar affective disorder, elevated Cho, NAA, and MI levels in the basal ganglia as well as elevated levels of glutamate (Glu) in the parietal lobes have been described.^{37, 212}

Children with attention deficit hyperactivity disorder (ADHD) demonstrate abnormally elevated NAA/Cr, Glu/Cr, and Cho/Cr ratios in the frontal lobes when compared with age-matched controls.³⁷

In patients with ALS, the NAA/Cr ratio is significantly decreased in the motor and premotor cortices, and similar decreases are present in the brain stem.^{21, 59}

In Huntington's disease, a reduced NAA/Cho ratio is present in both the basal ganglia and the cerebral cortex, and Lac elevations in these areas may also be present.^{114, 199}

MRS evaluation of the parkinsonian syndromes has revealed typical absence of metabolic abnormalities in the basal ganglia in idiopathic Parkinson's disease, as opposed to reductions in the basal ganglia NAA/Cr and NAA/Cho ratios in other parkinsonian syndromes such as progressive supranuclear palsy and corticobasal degeneration.¹⁹⁹

Certainly, the range of applications of proton MRS in the diagnosis and therapeutic monitoring of CNS disease will continue to grow as clinicians become more aware of the tremendous clinical potential of this imaging technique.

Phosphorus Magnetic Resonance Spectroscopy

Although much work has been performed to date utilizing ³¹P MRS, applications to the CNS have constituted only a small fraction of this work; applications involving muscle tissue, liver, heart, and even other organs have been studied. Since a thorough discussion of phosphorus MRS is beyond the scope of this chapter and since the overall clinical utility of this modality is much lower than that of proton MRS because of a decreased signal-to-noise ratio and poorer spatial resolution, only a brief introduction to its applications to the study of the brain is provided.

The seven major metabolite peaks that can be detected in phosphorus MR spectra of the brain include the following¹¹⁶:

- Three peaks of ATP, seen at approximately -7.8, -16.3, and -2.7 ppm (known as alpha, beta, and gamma ATP peaks, respectively)
- Phosphocreatine (PCr) peak, seen at 0 ppm
- Phosphodiester (PDE) compounds peak, seen at 2.6 ppm
- Inorganic phosphate (Pi) peak, seen at 4.9 ppm
- Phosphomonoester (PME) compounds peak, seen at 6.5 ppm

All of these are markers of energy utilization and transfer within the cells, and levels of these compounds are affected by intracellular energy balance. PCr serves as a high-energy phosphate storage compound in brain and muscle tissue, whereas PME and PDE compounds are found in membrane phospholipids and are involved in cell membrane synthesis and degradation. Elevations in PME compounds have been noted in cases of rapid cell membrane synthesis, such as in tumors and in normal developing infant brain (levels of PDE compounds are low in infants). Levels of PME compounds decrease whereas PDE com-

pounds increase from birth to approximately 3 years of age, when these levels stabilize.

The chemical shift of the Pi peak relative to the PCr peak has been used to determine intracellular pH, since it is pH-dependent. Multiple studies have shown that the pH of normal brain varies from 6.95 to 7.03.^{6, 31, 93, 103, 106, 115, 224} Little variation in pH between gray and white matter is noted, and brain tumors consistently demonstrate elevations in pH relative to normal brain tissue.^{31, 115}

Several studies have shown that tumor differentiation based on tissue pH is not possible.^{6, 31, 93, 224} Findings regarding alteration of the concentrations of the metabolites PCr and Pi in gliomas have been inconsistent and inconclusive.¹¹⁵ However, PDE is decreased in all gliomas relative to normal brain tissue, and its levels are higher in patients with GBM than in those with lower-grade tumors.^{6, 103} In addition, markedly elevated PME levels have been described in GBM.^{6, 31, 93, 171, 211} In addition, both the PME:ATP and PDE:ATP ratios tend to be elevated in glial tumors, particularly in GBM.^{31, 115, 201} Higher-grade tumors also demonstrate relatively elevated PME peaks and relatively decreased PDE peaks, which probably signify increased cell turnover.¹¹⁵

Studies utilizing ³¹P MRS in patients with epilepsy have shown ictal increases in Pi and Lac and decreases in PCr and pH in TLE.^{120, 216, 260} Postictally, pH is noted to increase with development of alkalosis prior to Lac normalization.^{120, 219} Interictal increased pH in the temporal lobe ipsilateral to the seizure onset has been noted in adults with TLE.²²³ In addition, ipsilaterally increased Pi and decreased PME without significant differences in other metabolites have been noted in TLE.^{105, 134, 223} In neonates, Younkin and coworkers have noted a 50% decrease in the PCr/Pi ratio in the seizure region with reestablishment of normal ratio postictally.²⁶¹ Studies of frontal lobe epilepsy have shown elevated pH and decreased PME in the affected frontal lobe.¹³⁰

Additional applications of ³¹P MRS have been described, particularly in pediatric neuroradiology. These and additional applications of phosphorus MRS, undoubtedly, will continue to evolve in the near future in light of the unique metabolic information that can be provided by this physiologic MR modality.

Other Nuclei and Functional Magnetic Resonance Spectroscopy

Spectroscopy using nuclei other than ¹H and ³¹P has been performed for the study of CNS disease. The nuclei that have been used for this purpose include carbon 13 (¹³C), sodium 23 (²³Na), and fluorine 19 (¹⁹F). However, since none of these nuclei has been used widely for clinical applications, they are not discussed in this chapter.

Another exciting research application of MRS is functional MRS, which enables evaluation of temporal changes in metabolite concentrations during visual and auditory stimulation or performance of language tasks.¹⁹⁵ A special fast spectroscopic imaging technique, called proton echo-planar spectroscopic imaging (PEPSI), has been used by Richards and colleagues to study language activation during performance of a silent verb generation task.¹⁹⁰ In-

creases in Lac and Cr have been noted in the left temporal lobe during this language task, and transient elevation of Lac has also been noted during visual and auditory stimulation in the respective sensory cortices.^{190, 195} Functional MRS is a promising new method for studying brain activation that may complement other techniques, such as functional MRI, magnetoencephalography, and PET, which are currently in widespread use for the study of transient physiologic changes in the brain.

Meningeal Processes

Melanie B. Fukui, Carolyn Cidis Meltzer

Anatomy and Embryology Meninges

The meninges, which form the coverings of the brain and spinal cord, develop from the *meninx primitiva*.⁶⁸ The neural tube is surrounded by this dense cellular layer, the *meninx primitiva*, shortly after the neural tube closes.¹²² As early as 32 days and as late as 44 of gestation, the primitive meninx begins to cavitate to form the cerebral cisterns by gradually decreasing its cellular component and enlarging its intercellular space.¹²² The periphery of the *meninx primitiva*, however, develops more dense cellularity to become the primitive *dura mater*.¹²²

The earliest subarachnoid space (SAS) is that ventral to the brain stem.¹²² As this space expands, the preponthodullary cisterns and anterior spinal SAS are formed.^{122, 155} At approximately 41 days, the space is extended to create perimesencephalic and dorsal mesencephalic cisterns.^{121, 122, 155} The primitive meninx is composed of totipotent mesenchymal cells of neural crest origin.⁶⁸ The remnants of incomplete differentiation of these pluripotent cells may be seen as deposits of fat, or lipomas, in and around the basal cisterns, corpus callosum, and cavernous sinuses.¹⁵⁵ The order of regression of the primitive meninx is reflected in the distribution of lipomas, as described by Salvi.¹⁵⁵ Thus, intracranial lipomas are thought most appropriately to represent developmental, rather than neoplastic, pathology of the meninges.¹⁵⁵

This network of concentric membranes consists of the *pachymeninx* (*dura mater*) and the *leptomeninges* (*arachnoid* and *pia mater*) (Fig. 12-1). The *dura mater* is the most superficial membrane, a thick, tough structure composed of dense connective tissue.²¹ The *dura* is composed of 2 lay-

ers: (1) an outer periosteal layer, which is highly vascularized, serves as the true periosteum of the inner table of the calvaria, and is not of meningeal origin,¹⁴² and (2) an inner meningeal layer, derived from the *meninx*. The cranial dural layers split to form the venous sinuses.

The term *dura* (from Latin, *durus*, meaning "hard") is an apt descriptor of the structure that maintains the position of the cerebral hemispheres and posterior fossa structure by its reflections, such as the *falx cerebri* and *tentorium cerebelli*. The *arachnoid* and *pia mater* constitute the *leptomeninges* (from Greek, *lepto* and *meninx*, meaning slender membrane). The delicate *arachnoid* is adjacent to the inner surface of the *dura* and is thinner over the convexities than at the base of the brain. The *pia mater* is a fine membrane that extends into the depths of the sulci.

Extra-axial Spaces

The meninges delimit the extra-axial compartments of the central nervous system (CNS). The epidural space is created when the *dura* is separated from the calvaria. Although the subdural space (between the *dura* and *arachnoid* membranes) has conventionally been characterized as a potential space containing minimal fluid, cells of the *arachnoid* actually form an intimate network with those of the meningeal dural layer.⁴⁶ Electron microscopy has provided evidence that cells belonging to the inner dural layer may be found on *both* sides of this space when collections form in the subdural space.^{46, 64} The subdural space, therefore, is formed by cleavage through the inner layer of the *dura* rather than by a true separation of *dura* and *arachnoid* and, as such, probably exists only in pathologic states.⁶⁴

Figure 12-1. Schematic representation of the *dura* and *leptomeninges*. PIA, *pia mater*. (From Meltzer CC, Fukui MB, Kanal E, Smirniotopoulos JG: MR imaging of the meninges: Part 1. Normal anatomic features and nonneoplastic disease. *Radiology* 201; 297-308, 1996.)

Figure 12-2. Diagram illustrating the anatomy of the perivascular (Virchow-Robin) space with respect to the pia mater and the subarachnoid space. (Modified from Fukui MB, Meltzer CC, Kanal E, Smirniotopoulos JG: MR imaging of the meninges: Part 2. Neoplastic disease. Radiology 201:605-612, 1996.)

The SAS (between the arachnoid and pia mater) contains cerebrospinal fluid (CSF) that flows throughout the CNS and drains into the venous sinuses through the valves of the arachnoid granulations.¹⁴² The pia and the arachnoid are joined by fine connective tissue and cellular septa that traverse the SAS.¹⁹ Near the base of the brain, though, the pia and arachnoid widely separate to accommodate the basal cisterns. Perivascular, or Virchow-Robin, spaces were originally thought to be potential pathways connecting the CSF and deep brain structures by virtue of continuity with the SAS.⁴¹ More recent studies, however, have concluded that perivascular spaces are within the subpial space, separated from the SAS by pia mater³ (Fig. 12-2).

Extra-axial Collections

Fluid collections in the epidural space assume a localized biconvex configuration as a result of the strong force needed to detach the firmly adherent dura from the inner table of the calvaria. The outer dural layer is most tightly adherent at sutures; classic teaching therefore holds that epidural collections do not cross suture lines.⁶⁰ Uncommon exceptions to this rule do occur, however. After administration of paramagnetic contrast medium, the dura adjacent to an epidural hematoma (EDH) has a curvilinear, enhancing appearance. An inflammatory reaction, with formation of granulation tissue on the outer surface of the dura, may produce increased thickness and intensity of enhancement in the dura immediately subjacent to an EDH, as demonstrated in Figure 12-3.⁶⁷

Greater tissue contrast and multiplanar imaging capability contribute to the superior sensitivity of magnetic resonance imaging (MRI) compared with computed tomography (CT) in detecting small subdural fluid collections.⁸⁵ MRI is especially useful in cases of subacute subdural hematoma (SDH), which may appear isodense to cortex on CT. Subdural hygromas result from leakage of CSF into the subdural space, probably after a tear in the arachnoid. MRI can distinguish subdural hematoma from subdural hygroma by improved detection of blood products, which are absent in a hygroma, but it cannot distinguish simple

from infected subdural fluid, however, since peripheral dural enhancement may be seen in both infected and noninfected subdural collections (Fig. 12-4). A diffusely enhancing, infected subdural collection may mimic an en plaque meningioma.¹⁰²

Imaging Imaging Modalities

MRI is substantially more sensitive than CT for visualizing both normal and abnormal meninges^{37, 55, 70, 104, 152, 154}

Figure 12-3. Epidural abscess. Enhanced axial T1-weighted image shows a lentiform epidural collection of pus with dural enhancement (arrows) that could mimic an epidural hematoma.

Figure 12-4. Subdural empyema. *A* and *B*, Enhanced axial CT images at the level of the falx cerebri show dural enhancement surrounding a subdural empyema.

(Fig. 12-5). Beam-hardening and other artifacts adjacent the calvaria may be partly responsible for the diminished detection of meningeal enhancement with CT. Experimental evidence suggests, in addition, that more intense enhancement results in areas of blood-brain barrier disruption with gadolinium-DTPA-enhanced MRI than with CT performed after iodinated contrast.^{92, 136}

It has been suggested that MRI may be equally sensitive or even superior to CT in detecting subarachnoid hemorrhage (SAH) in the subacute and chronic phases and when a fluid-attenuated inversion recovery (FLAIR) pulse sequence is used.^{115, 117} Other evidence suggests that FLAIR

sequences may result in false-negative interpretations in the setting of SAH.¹⁶⁷

Normal Meninges on Magnetic Resonance Imaging

The normal meninges may demonstrate short segments of thin, low signal intensity on standard spin-echo sequences.⁴³ Intravenous (IV) administration of gadolinium-DTPA results in enhancement of the normal cranial dura, which lacks a blood-brain barrier, in an interrupted pattern of short linear

Figure 12-5. Superior sensitivity of MRI over CT in detection of meningeal disease: Pott's puffy tumor. *A*, Enhanced axial CT image at the level of an extracranial subperiosteal collection of pus. *B*, Enhanced axial MR image obtained after administration of gadolinium at the same level shows enhancement of the subjacent dura/arachnoid (arrows). Detection of this meningeal enhancement prompted a change of antibiotics to improve cerebrospinal fluid drug penetration.

segments that is typically most prominent parasagittally^{27, 152} (Figs. 12-6 and 12-7). Field strength may influence the conspicuity of "normal" meningeal enhancement as well as the detection of pathologic enhancement. Earlier literature reported a distinct lack of enhancement of normal meningeal structures with relatively low-field-strength MRI.²⁰ The greater signal-to-noise levels achieved at relatively higher field strengths potentiate increased detection of meningeal enhancement (see Fig. 12-6).

Cohen and colleagues²⁷ reported that when meningeal enhancement was present on more than three contiguous 1.5 Tesla (T) spin-echo MR images, it was highly correlated with significant intracranial abnormality. Thick, long, or intensely enhancing segments, as well as nodular meningeal enhancement, are particularly suspect. The normal falx and dura may occasionally enhance in a thin uniform pattern.⁸⁶ The typical lack of normal meningeal enhancement observed in MRI of the spine may reflect the absence of the vascular outer dural layer that is found in the cranial pachymeninx.

Technique

The selection of MRI has a significant impact upon the conspicuity of normal meningeal enhancement and sensitivity in detecting meningeal disease (see Figs. 12-6 and 12-7). Numerous factors influence the appearance of the meninges on MR images, including (1) the presence and amount of MR contrast agent administered, (2) the type of

pulse sequence performed, and (3) the exact pulse sequence parameters.

For partial saturation (spin echo or gradient echo), short echo time (TE) sequences, crucial imaging parameters include the repetition time (TR) and excitation flip angle. The shorter the TR, the greater the degree of saturation of magnetization (i.e., decreased signal intensity) from all imaged tissues. As a result, contrast-enhancing tissue will be more conspicuous against the more saturated (i.e., hypointense) background tissues on a typical short TR, large flip angle gradient-echo study than on a spin-echo study. Therefore, the normal meninges usually exhibit diffuse enhancement on such ultrashort TR, large flip angle gradient-echo imaging sequences⁴³ (see Fig. 12-7). Imaging plane also affects visualization of meningeal enhancement; the coronal plane is preferred to axial MRI data for evaluating meningeal enhancement over the cerebral convexity.

Similarly, factors that either increase the signal from the meninges or decrease signal from background tissues enhance the contrast-to-noise ratio (CNR) and, therefore, the conspicuity of the enhancing meninges. Double-dosing and triple-dosing of paramagnetic contrast agents have demonstrated improved detection of parenchymal lesions with MRI,⁶⁹ and there is evidence to support a similar dose effect for enhanced MRI of meningeal disease.^{82, 83, 137} More recently, cases of leptomeningeal metastases that had been diagnosed by MRI and high-dose (0.3 mmol/kg) gadolinium have been reported that were not visualized with standard dose (0.1 mmol/kg) technique (Fig. 12-8).^{59, 83} Also, the use of fat saturation or magnetization transfer

Figure 12-6. Effects of field strength on conspicuity of normal meningeal enhancement. A, Axial T1-weighted image acquired at 0.5 T immediately after injection of 0.1 mmol/kg gadolinium. B, Axial T1-weighted image acquired at 1.5 T, one day later, in the same patient, immediately after injection of the same dose of gadolinium shows more prominent enhancement of the falx (arrows) than in A. (From Meltzer CC, Fukui MB, Kanal E, Smirniotopoulos JG: MR imaging of the meninges: Part 1. Normal anatomic features and nonneoplastic disease. *Radiology* 201:297-308, 1996.)

Figure 12-7. Effects of and pulse sequence on conspicuity of normal meningeal enhancement. *A*, Axial T1-weighted spin-echo image in another patient shows faint, short segment meningeal enhancement (*arrow*). *B*, Axial, spoiled-gradient, recalled-echo image in the same patient shows thin, continuous enhancement in a dura/arachnoid pattern. (From Meltzer CC, Fukui MB, Kanal E, Smirniotopoulos JG: MR imaging of the meninges: Part 1. Normal anatomic features and nonneoplastic disease. *Radiology* 201:297-308, 1996.)

options increases the CNR by decreasing the signal from the background tissues.^{38, 137}

The optimal imaging protocol for detection of meningeal disease is based on (1) sensitivity, (2) technique, (3) role, (4) cardinal signs, and (5) principal patterns (Table 12-1).

Sensitivity of Magnetic Resonance Imaging

In the past, unenhanced spin-echo MRI was insensitive in detecting meningeal disease.¹⁰⁴ The advent of the FLAIR sequence has greatly improved the sensitivity of MRI performed in the absence of gadolinium to detect meningeal and SAS abnormalities.^{145, 167} Singer and coworkers evaluated the use of FLAIR MRI in 62 patients (21 with proven SAS or meningeal disease) and 41 control patients.¹⁴⁵ The sensitivity, specificity, and accuracy of FLAIR for SAS disease were 85%, 93%, and 90%, respectively.¹⁴⁵ Although

all six cases of acute SAH were interpreted as abnormal on FLAIR images in the Singer series, this was a source of false-negative interpretation in the series by Williams and associates.^{145, 167}

Poor detection of SAH has been attributed to the relatively high oxygen tension in the SAS, which does not permit evolution to deoxyhemoglobin⁹² and to the diluting effect of CSF. In 24 patients who underwent both FLAIR and gadolinium-enhanced T1-weighted MRI, FLAIR imaging (sensitivity, specificity, and accuracy, 86%, 91%, and 89%, respectively) was superior to gadolinium-enhanced T1-weighted imaging (43%, 88%, and 74%).¹⁴⁵

Williams and coauthors¹⁶⁷ prospectively evaluated 376 consecutive cases performed with FLAIR imaging and showed that FLAIR may result in false-negative diagnoses of meningeal or SAS disease in cases of infectious meningitis, carcinomatosis, and SAH.¹⁶⁷ In this series, a false-positive diagnosis of meningeal or SAS pathology was made in the presence of normal and hyperintense cortex, susceptibility artifact, prominent pial vessels, concatenated saturation pulse, or flow artifact.¹⁶⁷ Neoplastic or inflammatory processes involving the SAS are best evaluated with paramagnetic contrast agents for visualization of enhancement of the accompanying meningeal involvement (Fig. 12-9).

Role of Imaging

Before and after gadolinium administration, MRI plays an important role in the diagnosis of meningeal neoplasm

Table 12-1. Protocol for Magnetic Resonance Imaging Performed at 1.5 Tesla

Axial FLAIR image
Axial T1-weighted image
Axial and coronal T1-weighted image after administration of a double or a triple dose of gadolinium with a fat-saturation pulse or magnetization transfer

FLAIR, fluid-attenuated inversion recovery.

Figure 12-8. Effect of contrast dose on meningeal enhancement. Axial T1-weighted images obtained after administration of 0.1 mmol/kg (A) and 0.2 mmol/kg (B) doses of gadolinium show increased enhancement in a pia/subarachnoid space pattern at the higher dose in this patient with carcinomatosis of the meninges from gastric carcinoma.

Figure 12-9. Axial fluid-attenuated inversion recovery (FLAIR) image in a patient with leptomeningeal spread of breast carcinoma (A) shows signal abnormality in a pia/subarachnoid space pattern (arrowheads) that enhances on the T1-weighted image after administration of gadolinium (B).

in the asymptomatic patient when CSF cytologic examination results are equivocal, or when lumbar puncture is contraindicated.^{23, 47, 52, 152} Imaging, however, does not replace CSF examination in diagnosis of meningeal neoplasm.

The limited sensitivity of CSF cytologic examination continues to be a significant obstacle and reinforces the complementary role of imaging.⁵³ The percentage of positive spinal CSF cytology in cases of primary CNS tumors with histologically confirmed meningeal involvement varies from 12% to 63% and is increased in symptomatic patients.^{6, 56, 89, 112} With meningeal metastases from non-CNS neoplasms, CSF cytology was positive in between 45% and 80% of cases with higher yields after multiple spinal taps.^{118, 161} The modest sensitivity of CSF cytology has fueled the search for CSF tumor markers to detect dissemination of neoplasm. Like CSF cytology, tumor detection with CSF markers is also restricted by suboptimal sensitivity and specificity.^{114, 157}

The sensitivity of MRI in detecting meningeal neoplasm was originally reported to be lower than that of CSF cytology, with high false-negative rates: 30 to 33% for MRI and 58% for CT.^{24, 173} The early studies, however, may have unwittingly introduced a selection bias by using positive cytology as an inclusion criterion.^{24, 173} Later series comparing CT myelography with MRI showed an increased detection rate of CSF metastases with MRI (65% to 72%) compared with CT myelography (45% to 47%) and with cytology (29%).^{70, 91}

A more recent Memorial Sloan-Kettering Cancer Center study⁴⁷ showed that when the patient cohort was not restricted to patients with positive cytologic findings, the rate of detection of meningeal carcinomatosis was increased. This study examined 137 patients with signs and symptoms of meningeal disease.⁴⁷ CT and MRI were assessed for signs of meningeal or SAS neoplasm, including hydrocephalus, enhancement of the dura, leptomeninges, and cranial nerves.⁴⁷ Leptomeningeal metastases were identified in 77 of 137 patients.⁴⁷ The diagnosis of leptomeningeal metastases was based on the clinical and imaging findings *alone*, in 31% of those cases.⁴⁷ Abnormal imaging findings were reported much more frequently in cases of solid tumor primaries (90%) than in hematologic neoplasms (55%).⁴⁷ A caveat in using MRI for the diagnosis of leptomeningeal tumor involvement, then, is that MRI is less sensitive in detecting involvement of the meninges resulting from hematologic malignancies in contrast to detecting solid tumors.^{24, 47, 173}

When the distinction between meningeal neoplasm and inflammatory meningeal disease cannot be established by CSF and clinical data, MRI can support the diagnosis of neoplasm and guide meningeal biopsy.^{80, 96} Although infectious meningitides are often uncovered by CSF analysis, MRI may be used to target meningeal biopsies when needed.

Cheng and coworkers²⁶ reported an improved yield from meningeal biopsy specimens in cases of chronic meningitis when tissue specimens were obtained from enhancing regions identified on MRI (Fig. 12–10). MRI has an advantage over CSF examination in its ability to characterize bulky neoplastic disease that may be more responsive to radiation therapy.²³ Because CSF cytologic examination

Figure 12–10. Chronic meningitis. Thick, slightly irregular dura/arachnoid enhancement on axial T1-weighted imaging proved to be idiopathic hypertrophic pachymeningitis on biopsy.

produces a higher false-negative rate in focal (rather than diffuse) disease,^{13, 53} imaging may be of particular value in detecting focal spread of neoplasm to the meninges or SAS. MRI also has the potential to allow noninvasive monitoring of treatment response, although it is conceivable that the imaging abnormalities may persist beyond the eradication of neoplastic cells in the CSF.¹⁶⁹ In a series of patients with coccidioidal meningitis, diminution of meningeal enhancement was seen in treated patients with improving CSF profiles.¹⁷¹ Therefore, MRI also may be useful as a means of monitoring a response to therapy in fungal meningeal disease.¹⁷¹

Imaging is a useful adjunct for the diagnosis of neoplastic meningeal disease in the appropriate clinical setting along with CSF examination to exclude infectious or noninfectious processes of the meninges.⁴⁷

Finally, imaging may allow the clinician to assess outcome, since diffuse leptomeningeal involvement confers a poor prognosis.¹⁴

Cardinal Signs

The main imaging findings that have been associated with meningeal pathology are as follows^{30, 40, 47, 78, 91, 132, 151, 152, 173:}

- Hydrocephalus (Fig. 12–11)
- Dura and arachnoid enhancement or signal abnormality (see Fig. 12–10)
- Pia and SAS enhancement or signal abnormality (see Fig. 12–11)

Figure 12-11. Hydrocephalus and pia/subarachnoid space abnormality. Enlargement of the temporal horns of the lateral ventricles and a pia/subarachnoid enhancement pattern over the cerebellum indicates meningeal spread of lung carcinoma.

Figure 12-12. Ependymal enhancement. Thin, linear enhancement of ependyma (arrowheads) on T1-weighted imaging in addition to pia/subarachnoid enhancement is present in this patient with disseminated small-cell lung carcinoma.

Figure 12-13. Focal, nodular ependymal enhancement. A, Nodular enhancement of the ependyma of the frontal horns was the probable entry point for subarachnoid spread of melanoma. B, Sagittal T1-weighted image of the lumbar spine shows nodular, enhancing drop metastases to the cauda equina (arrowheads).

Figure 12-14. Diffuse, nodular pia/subarachnoid space enhancement. A and B, Multiple pial-based enhancing nodules are present in this patient with disseminated lung carcinoma.

- Subependymal enhancement or signal abnormality (Fig. 12-12)

Hydrocephalus may or may not be associated with enhancement of the meninges or ependyma. In this setting, hydrocephalus alone implies a resorptive block to CSF flow. Hydrocephalus may occur in the setting of SAH, infectious or noninfectious meningitis, and, of course, neoplasm. In the patient with neoplastic meningeal disease, hydrocephalus is more likely when leptomeningeal invasion or SAS has occurred rather than when neoplasm is limited to the dura.¹⁶²

Enhancement of the meninges may occur in the spine or brain. Meningeal or subependymal enhancement may be focal (Fig. 12-13) or diffuse (see Fig. 12-12) and may have either a smooth or nodular contour (Fig. 12-14; see Fig. 12-13). Diffuse leptomeningeal involvement is a harbinger of a worse prognosis than focal disease.¹⁴ Although a nodular pattern of enhancement may suggest neoplasm, it is not specific, since non-neoplastic entities such as sarcoidosis may also produce nodular thickening of the meninges (Fig. 12-15B). Infiltration of the leptomeninges overlying the convexities or in the basal cisterns may result in sulcal or cisternal obliteration on a non-contrast T1-weighted image (Fig. 12-16) or a FLAIR sequence (see Fig. 12-9). Minimal shortening of T1 and T2 relaxation times in the cisternal CSF (“dirty CSF sign”) may be seen on unenhanced MR images¹⁶ (see Fig. 12-16). In rare instances, subarachnoid tumor or inflammatory exudates may result in distention of the SAS (Fig. 12-17).

Imaging Patterns

Two distinct patterns of meningeal enhancement or signal abnormality may be observed with MRI. The *dura*/

arachnoid pattern follows the inner contour of the calvaria (Fig. 12-18), whereas the *pia mater*/SAS abnormality extends into the depths of the sulci (Fig. 12-19). Enhancement or signal abnormality surrounding the brain stem is always of the pia mater/SAS type, since the arachnoid is clearly separated from the pia mater by the intervening basal cisterns in this region. Although pia mater/SAS enhancement does occur more commonly in the setting of meningitis than with tumor involvement, both inflammatory and neoplastic processes may demonstrate either pattern.^{87, 128} A diffuse appearance favors an inflammatory etiologic mechanism, whereas nodular meningeal enhancement suggests a neoplasm (Tables 12-2 to 12-6).

Williams, M.D., University of Pittsburgh Medical Center, Pittsburgh, Pa.)

Dura/Arachnoid Pattern

Because the dura and arachnoid are closely approximated, the distribution of meningeal enhancement does not reliably distinguish purely pachymeningeal (dural) from leptomeningeal (arachnoidal and pial) involvement. As a

result, the dura/arachnoid pattern of enhancement does not imply that the leptomeninges or the SAS is spared. This fact has practical importance because some authors report a lower incidence of positive CSF cytologic findings with the dural pattern, in contrast to the pial pattern, implying a lack of subarachnoid space neoplasm.¹²³

A surprisingly moderate rate (55%) of positive CSF cytologic results was reported in a subset of 11 patients with a dura/arachnoid enhancement pattern on MRI.⁴⁷ The presence of malignant cells in the CSF of patients in this subgroup implies neoplastic involvement of the arachnoid and SAS. This confirms the limitation of MRI in distinguishing abnormal enhancement of the dura from that of the arachnoid.⁴⁷ When restricted to the dura, however, meningeal carcinomatosis often results in negative CSF cytology; in this setting, MRI can play an important role in disease detection.

The dural tail sign, once considered specific for meningioma, may be observed in a wide variety of other extra-axial lesions, including schwannoma (Fig. 12-20), dural metastases (Fig. 12-21), lymphoma, tuberculoma, and sarcoidosis.¹⁰⁶ Occasionally, a dural tail may be seen in association with intra-axial mass lesions, such as gliomas or non-CNS metastases.¹⁰⁶ Although this imaging feature has been useful in suggesting the diagnosis of meningioma, its lack of specificity may occasionally cause misleading interpretation of MR images.¹⁰⁶ Similar signal, shape, and enhance-

After gadolinium administration (C), there is extensive pia/subarachnoid space enhancement on the coronal image.

ment characteristics found with several of these lesions may further confound the distinction between meningiomas and other entities.¹⁰⁶

Pia Mater/Subarachnoid Space Pattern

Similarly, the pia mater/SAS pattern of enhancement may reflect neoplasm within the SAS, tumor infiltration of the pia mater, or both.¹⁷³ The pia mater/SAS pattern is more common in patients with infectious meningitis than in those with a neoplasm,^{87, 128} although the pia mater/SAS distribution is not at all specific for inflammation.

A higher rate of positive CSF cytologic findings has

been reported in conjunction with the pia mater/SAS pattern than with the dura/arachnoid pattern of enhancement in cases of neoplasm.¹²³ This may reflect the anatomy of the blood-brain barrier with respect to the meninges.⁸⁷ The dura lacks a blood-brain barrier, since its capillary endothelium has a discontinuous cell layer, whereas the outer layer of the arachnoid has capillaries with a continuous cell layer and tight junctions.^{139, 140} Bloodborne neoplastic cells, therefore, may gain access to the dura more easily than to the SAS.⁸⁷ A pia mater/SAS pattern may reflect SAS enhancement, pial enhancement, or both.⁴⁵ Gadolinium may leak through capillary tight junctions that have been disrupted by neoplastic invasion of the meninges⁴⁵ and directly enter the CSF.

Non-neoplastic Meningeal Disease**Infectious Meningitis****Bacterial Meningitis**

Bacterial meningitis results either from hematogenous spread of infection or, occasionally, from direct extension from a paranasal sinus or mastoid source.⁸⁸ The mechanism

of entry of bacteria from the intravascular space into the CSF is not well understood.

Animal studies have suggested that bacterial cell wall elements provoke an inflammatory response that brings about opening of tight intercellular junctions in the arachnoid capillary bed.⁸⁷ This breakdown in the leptomeningeal blood-brain barrier allows the bacteria to gain access to the SAS. Early congestion and hyperemia of the lepto-

Figure 12-17. Perivascular space pattern. Axial T2-weighted image (A) and enhanced T1-weighted image (B) show distention of the perivascular spaces at the base of the brain by the gelatinous, nonenhancing pseudocysts of cryptococcosis.

meninges are succeeded by mixed inflammatory cell infiltration with exudate in the subarachnoid space, especially over the cerebral convexity (see Fig. 12-16).

A link between meningeal enhancement and the degree of inflammatory cell infiltration of the leptomeninges has been proposed by Mathews and coworkers.¹⁰⁴ The lack of gadolinium enhancement in some areas of minimal inflammation suggests a threshold effect, whereby a critical degree of inflammatory reaction is required before meningeal enhancement may be observed.¹⁰⁴ MRI is superior to CT in the evaluation of complications of meningitis, including subdural empyemas, dural venous thrombosis, secondary ischemia, and parenchymal lesions.²⁵ Septic thrombosis of the superior sagittal sinus, although uncommon since the advent of antibiotics, may complicate bacterial meningitis¹⁴⁷ (Fig. 12-22).

When thrombosis is suspected, MRI is the imaging modality of choice for confirming the presence of throm-

bus. Absent flow may be detected as lack of a normal flow void in the sagittal sinus on short TR images and optimally demonstrated by magnetic resonance angiography (MRA) using two-dimensional (2D) phase-contrast techniques.⁸¹ Conversely, localized meningeal enhancement may also be seen overlying an adjacent parenchymal infectious process, such as a brain abscess or encephalitis. Bacterial meningitis may result in ventriculitis, especially in the setting of gram-negative and iatrogenic infections.⁴⁸ An early finding in ventriculitis may be that of irregular debris in the dependent portions of the ventricles⁴⁸ (see Fig. 12-16). Infectious meningeal processes may occasionally spread across the pial barrier to cause cerebritis.

Mycobacterial Meningitis

CNS tuberculosis is increasing in frequency, partly as a result of its proclivity to occur with human immunodeficiency virus (HIV) infection. Tuberculous meningitis commonly occurs as a result of disseminated pulmonary infection, usually along with parenchymal brain involvement, although it rarely may be seen as the sole manifestation of the disease.¹⁰⁷ In contrast to bacterial meningitis, tuberculous infection is associated with a more insidious onset, fewer changes in the CSF profile, and higher rates of mortality and complications, such as infarction. Although tuberculosis tends to involve the basal meninges, tuberculomas may occur within the brain parenchyma or subarachnoid, subdural, or epidural spaces^{16, 129} (Fig. 12-23). In one series, meningeal enhancement was observed in 36% of HIV-infected patients with CNS tuberculosis evaluated with MRI.¹⁶⁵

MRI of tuberculous meningitis demonstrates meningeal enhancement, most often in the basal cisterns, reflecting the known predilection of tuberculosis for the base of the brain. Calcification of the basal meninges may also be seen and is more easily appreciated with CT than with MRI.

Figure 12-21. Focal dura/arachnoid mass. CT scan (A) shows metastatic breast carcinoma to the calvaria (arrow) extending to the dura on an enhanced axial T1-weighted image (B) (arrows).

Focal or diffuse dura/arachnoid enhancement may be observed on contrast-enhanced MRI scans of the spine in cases of suspected active tuberculous meningitis.⁹³ Thickening, inflammation, and fibrosis of the leptomeninges are commonly seen at histopathologic examination.

Meningitis may also be caused by a virus or fungus, a fact that is of particular importance in immunocompromised patients. In patients with acquired immunodeficiency syndrome (AIDS), a polyradiculomyelitis may develop, in rare circumstances, as a result of cytomegalovirus (CMV) or varicella-zoster virus infection.⁵¹ Diffuse enhancement of the cauda equina on MRI should alert the clinician to exclude these causes in AIDS patients.¹⁶⁴

Fungal Meningitis

Fungal meningitis usually results from hematogenous dissemination of disease and is also often seen in immuno-

suppressed hosts. Fungal meningitides, such as those caused by *Aspergillus*, *Cryptococcus*, and *Coccidioides*, may be demonstrated by contrast-enhanced MRI.^{105, 110, 171}

Aspergillosis is an important cause of morbidity and mortality in organ transplant recipients and may be associated with focal, thick dura/arachnoid enhancement that resolves with treatment.¹¹⁰

Cryptococcus frequently infects patients with AIDS, but meningeal enhancement is seen only occasionally in cryptococcal meningitis, probably because of the blunted host response.^{105, 141} Meningeal enhancement was observed in only one in five autopsy-proven cases of AIDS-related cryptococcosis studied with gadolinium-enhanced MRI.¹⁰⁵ Cryptococcal infection tends to spread from the basal cisterns via perivascular spaces to the basal ganglia, brainstem, internal capsule, and thalamus.¹⁶³ This produces a characteristic appearance on MRI scans of nonenhancing,

Figure 12-22. Diffuse dura/arachnoid enhancement. A, Coronal T1-weighted image shows dura/arachnoid enhancement (arrows) in a patient with meningitis and subsequent superior sagittal sinus thrombosis. B, There is an absence of flow in the superior sagittal sinus on a sagittal phase-contrast MR angiogram.

Figure 12-23. Multiple ring-enhancing tuberculomas are distributed throughout the perivascular spaces and basal pial surfaces on an axial T1-weighted image after administration of gadolinium.

dilated perivascular spaces, caused by infestation with the gelatinous pseudocysts of cryptococcal material (see Fig. 12-17).

In contrast to the pattern seen with *Cryptococcus*, Wrobel and colleagues¹⁷¹ reported MRI enhancement of the meninges in 7 of 11 patients with coccidioidal meningitis. Enhancement was most prominent in the basilar cisterns, the sylvian and interhemispheric fissures, and the upper cervical SAS. Spirochetal infections may exhibit both localized and diffuse meningeal enhancement.¹⁸ Similarly, smooth, diffuse pia/SAS enhancement of the brain stem and the entire spinal cord has been reported in Lyme disease, even in the absence of MRI evidence of parenchymal disease.³³

Aseptic Meningitis

Meningitis is designated "aseptic" when CSF cultures are sterile. Aseptic meningitis may have a variety of causes, including viral infection and irritation after introduction of foreign substances into the CSF (e.g., blood, chemical agents, or contrast materials), or it may be seen against the backdrop of connective tissue disorders.¹⁰⁷ MRI may demonstrate meningeal enhancement or subarachnoid signal abnormality (Fig. 12-24). In cases of suspected aseptic meningitis, performing MRI after administration paramagnetic contrast medium may help prevent delays in diagnosis.⁴²

Noninfectious Inflammatory Meningitis

Noninfectious granulomatous disease can also involve the meninges. Approximately 5% of patients with sarcoido-

sis have neurologic manifestations; of those, the most common sign is that of cranial nerve palsies.¹⁵⁰ Gadolinium-enhanced MRI is the study of choice to document meningeal involvement and may show either the pia mater/SAS or the dura/arachnoid^{143, 144, 174} (see Fig. 12-15). Striking thickening of the meninges may also be demonstrated. Sarcoid was present in 31% of 37 patients with chronic meningitis of unknown etiology examined with enhanced MRI and meningeal biopsy and, as such, was the most frequent cause of chronic meningitis in that series.²⁶

Meningeal abnormality may also occur in Wegener's granulomatosis¹³¹ (Fig. 12-25). Thickened, nodular meninges on both enhanced CT and MR images in a patient with Wegener's granulomatosis were reported by Tishler and colleagues.¹⁵³ The imaging features reflect the histopathologic findings of dural and brain biopsies that revealed granulomatous infiltration of the dura and development of fibrosis and granulomas of the pia mater and arachnoid.

Hypertrophic cranial pachymeningitis is a rare type of diffuse granulomatous inflammation that produces thickening, chronic inflammation, and fibrosis of the dura.^{101, 103} Common presenting symptoms include headache, cranial nerve palsies, and ataxia. Diffuse dural enhancement (on enhanced T1-weighted images) or hypointense and thickened dura (on T2-weighted images) may be demonstrated on MRI (see Fig. 12-10). Diagnosis requires confirmation with dural biopsy. The disease may progress despite corticosteroid therapy.

In rare instances, meningeal enhancement has been reported to accompany demyelinating disease. We are aware of two reports of meningeal enhancement on MRI in cases of multiple sclerosis (MS). One case displayed a diffuse dura/arachnoid pattern; the other showed focal pial enhancement.^{9, 32} Serial MRI of MS plaques suggests that parenchymal lesion enhancement is related to the inflammatory process associated with active demyelination.⁹ Analogously, meningeal enhancement in MS may result from extension of perivascular lymphoplasmacytic infiltration into the leptomeninges, found in 41% of autopsy cases.⁶³ A similar inflammatory etiology was proposed by Fulbright and coauthors⁴⁹ in describing enhancement of multiple cranial nerves in Guillain-Barré syndrome, a disorder characterized by peripheral demyelination.

Iatrogenic Meningeal Enhancement

Benign meningeal enhancement on MRI may result from mechanical disruption of the meninges from a variety of causes. Localized or diffuse dural enhancement may occur after craniotomy and may persist indefinitely.^{20, 37} (Fig. 12-26). It may be difficult to distinguish normal reactive postoperative enhancement from meningeal tumor involvement following craniotomy for tumor resection. Postoperative meningeal enhancement usually regresses over time, often resolving between 1 and 2 years after craniotomy.³⁷ In addition, the distribution of enhancement may support a benign etiologic mechanism.

In contrast to the typically basilar pattern of neoplastic meningitis, postoperative enhancement occurs more often over the convexities.²⁰ The morphology of enhancement may also provide clues as to the cause. A nodular dural

Figure 12-24. Aseptic meningitis. *A* and *B*, Thin, linear pia/subarachnoid space enhancement (*arrowheads*) is seen in a patient with headache and no organism growth on cerebrospinal fluid culture on axial and coronal enhanced T1-weighted images.

enhancement pattern or thick pia mater/SAS enhancement suggests recurrent tumor.⁷⁵ Placement of a ventricular catheter may also result in diffuse or localized dural enhancement. In rare instances, dura/arachnoid enhancement may result from uncomplicated lumbar puncture.¹⁰⁸ Dural enhancement after lumbar puncture occurs more commonly, however, when intracranial hypotension results, suggesting a CSF leak.¹⁵

Vascular Disease

Occasionally, an acute cerebral infarction may demonstrate adjacent meningeal enhancement (Fig. 12-27). This “meningeal enhancement sign” occurs between day 2 and day 6 after infarction. It is seen with large supratentorial infarcts and usually has a dura/arachnoid configuration.^{36, 39} Although the cause of meningeal enhancement in cerebral infarction is not established, possible contributing factors include reactive hyperemia and local inflammation following meningeal irritation.³⁶

Hemorrhage into the SAS also irritates the leptomeninges, causing inflammation of the pia mater and arachnoid.⁶⁶ In severe cases, fibrosis may ensue and, eventually, may obliterate the SAS. Superficial siderosis is a rare condition resulting from deposition of hemosiderin in the leptomeninges and surface of the brain following recurrent SAH and is a cause of hearing loss.^{22, 76, 79} The leptomeninges are thickened and pigmented on pathologic examination. A characteristic hypointense rim is observed along the brain surface on T2-weighted images^{17, 22} (Fig. 12-28). This hypointense border of hemosiderin deposits in superficial siderosis becomes exaggerated, and thus more readily detected, on gradient-echo MRI as a result of augmented magnetic susceptibility effects.⁷⁹ The thickened meninges may also enhance with gadolinium. Vasculitis rarely involves the meninges. Preferential involvement of small leptomeningeal vessels in granulomatous angiitis may result in meningeal enhancement.¹¹³

MRI is the modality of choice for evaluation of Sturge-Weber syndrome, a phakomatosis characterized by deranged vasculature of the face, brain, and meninges.¹⁴⁶ Poor venous drainage and chronic ischemic damage to the underlying cortex develop as a result of the leptomeningeal vascular malformation that originates in the subarachnoid space. MRI of the brain shows superficial gyriform enhancement. This enhancement likely results from slow flow within the leptomeningeal vascular malformation with or without enhancement of ischemic^{11, 160} (Fig. 12-29).

Meningioangiomas is a rare hamartomatous disorder of the leptomeninges, distinguished by meningovascular proliferation and leptomeningeal calcification.^{2, 65, 126} A cortical mass with meningeal extension and heterogeneous signal intensity on T2-weighted images and demonstrating contrast enhancement on MRI has been reported (Fig. 12-30).^{126, 166} Halper and coworkers⁶⁵ have theorized that meningioangiomas is caused by a proliferation of both meningotheial cells and leptomeningeal vessels within perivascular spaces as they penetrate the cortex.

A combined pia mater/SAS and dura/arachnoid pattern of enhancement has been rarely reported in association with migraine headaches.^{29, 97} This unusual finding is attributed to hyperperfusion, documented on single photon emission computerized tomography (SPECT) or transcranial Doppler imaging.^{29, 97}

Toxic Meningeal Enhancement

Chemical meningitis may arise following rupture of dermoid or epidermoid cyst. This inflammation is likely provoked by the irritating effect of cholesterol crystals and keratin material discharged into the CSF.^{31, 98} In such cases, the diagnosis of ruptured dermoid is usually verified by demonstration of droplets of high signal lipid material dispersed throughout the SAS on unenhanced T1W MR images.

Meningeal irritation resulting in contrast enhancement

Figure 12-27. Meningeal enhancement after infarction. A, Axial proton-density-weighted image shows the left frontal infarct. B, Sagittal T1-weighted image shows bright signal in the cortex of the left temporal infarct (arrows). C, There is gyriform enhancement on the axial T1-weighted image that is probably a combination of cortical and pial enhancement (arrows).

on MRI has also been reported in the setting of adverse drug reactions. Eustace and Buff⁴² reported a case of ibuprofen-induced meningitis depicted by meningeal enhancement on MRI. Meningeal enhancement persisted on repeated MRI scans 1 week later despite resolution of symptoms within 12 hours of drug cessation.

Spontaneous Intracranial Hypotension

Like the low intracranial pressure headache after complicated lumbar puncture, spontaneous intracranial hypo-

tension is identified by a postural headache that resolves after placement of an epidural blood patch.¹³⁵ A CSF pressure of less than 60 mm of water in the absence of previous lumbar puncture establishes the diagnosis.

MRI has shown striking, thick, diffuse dural/arachnoid enhancement.^{44, 74} Subdural fluid collections may occur in conjunction with this low-pressure state.¹³⁵ An unsuspected, spontaneous CSF leak may be the inciting factor (Fig. 12-31), and thus recognition of this combination of imaging and clinical findings should prompt a search for the source of leak. Identification of this treatable cause of

GRASS, gradient-recalled acquisition in a steady state.

Figure 12-31. Intracranial hypotension. Coronal T1-weighted image demonstrates diffuse dura/arachnoid enhancement in this patient who presented with severe headaches and whose CSF pressure was low on lumbar puncture. The axial T2-weighted image shows fluid, presumed to be cerebrospinal fluid in the soft tissues of the upper neck (arrows). The patient recovered after surgery despite the fact that, although myelography revealed a leak, the exact site could not be found at operation.

meningeal abnormality in association with the germane clinical features may prevent diagnostic delay and unnecessary meningeal biopsy.

Neoplastic Meningeal Disease

Primary Involvement

Primary dural neoplasms are rare. Neoplasms arising from the dura are mesenchymal in origin because the dura is composed of fibrous tissue.¹³⁸ Primary dural tumors bridge the entire range of benign (fibromas) to intermediate (fibromatosis) to malignant (sarcomas).¹³⁴ An assortment of dural sarcomas has been reported, including chondrosarcoma, fibrosarcoma, and malignant fibrous histiocytoma.^{5, 95, 100} Previous radiation therapy for another disease has been connected with some sarcomas.⁵

The most common primary tumor arising from the leptomeninges is meningioma (Figs. 12-32 and 12-33).¹³⁸ Meningiomas originate from meningotheelial cells of the arachnoid.¹³⁸ A hormonal influence has been implicated in the pathogenesis of meningiomas because they are more common in women than in men, occur more often in patients with breast cancer, and may become symptomatic during pregnancy.^{12, 77, 138} Radiation therapy has also been implicated as a causative factor in meningioma,^{50, 149} especially in patients treated for tinea capitis or vascular nevi in childhood. Fifty percent of meningiomas are isointense with gray matter on T1-weighted and T2-weighted im-

aging; the remaining half vary in signal intensity.¹⁴⁸ Heterogeneous signal intensity on MRI may result from calcification, vascular, or cystic components.¹⁴⁸

Additional primary leptomeningeal neoplasms, such as glioma (Fig. 12-34),^{34, 73, 96, 125} melanoma,⁴ melanocytoma

Figure 12-32. Focal, linear dura/arachnoid enhancement characterizes this right tentorial en plaque meningioma.

Figure 12-33. Meningiomatosis in neurofibromatosis, type 2 (NF 2). Meningiomatosis (multiple meningiomas) was found in this patient with diffuse, nodular dura and arachnoid enhancement.

Figure 12-34. Primary leptomeningeal gliomatosis. This rare primary malignant meningeal neoplasm was diagnosed only at autopsy. There is both linear and nodular enhancement in a pia/subarachnoid space pattern (*arrows*) on a coronal image (*A*) and a sagittal enhanced T1-weighted image (*B*). (Courtesy of Bernhard C. Sander, M.D., and Tibor Mitrovics, M.D., Freie Universitätsklinikum Rudolf Virchow, Berlin, Germany.)

Figure 12-35. Primary leptomeningeal melanocytosis. Sagittal T1-weighted images obtained before (A) and after (B) administration of gadolinium show multiple, tiny nodular foci of hyperintensity (arrowheads) along the pial surface of the cervical spinal cord with enhancement in this case of primary leptomeningeal melanocytosis. There is also an intramedullary lesion (curved arrow).

(Fig. 12-35),¹¹¹ sarcoma,^{127, 138} and lymphoma,⁹⁴ are very rare. Primary leptomeningeal gliomas probably originate from heterotopic rests of glial tissue within the meninges and SAS.^{28, 170}

Secondary Involvement

Breast carcinoma (CA), lymphoma, leukemia, lung CA, malignant melanoma, gastrointestinal CA, and genitourinary CA are the most common neoplasms to progress to

meningeal dissemination.^{71, 118, 161} Primary CNS neoplasms, such as medulloblastoma and primitive neuroectodermal tumor (PNET), pineoblastoma (Fig. 12-36), ependymoma, germ cell tumor (Fig. 12-37), astrocytoma (Fig. 12-38), and glioblastoma (Fig. 12-39), also have a propensity for meningeal spread.^{6, 7, 119, 120, 124} Most tumors tend to produce focal involvement in a dura/arachnoid or pia/SAS distribution. Exceptions to this are very aggressive tumors, such as lung and breast CA, that may result in diffuse meningeal neoplasm.

Figure 12-36. Subarachnoid spread of pineoblastoma. A and B, Coronal enhanced T1-weighted images show the pineal region mass with pia/subarachnoid space enhancement (arrows) in this patient with cerebrospinal fluid dissemination of pineoblastoma.

Figure 12-37. Disseminated germ cell tumor. This pineal region neoplasm demonstrates ependymal and subarachnoid spread involving the optic chiasm (arrowheads) on an enhanced coronal T1-weighted image.

Figure 12-38. Cerebrospinal fluid spread of astrocytoma in a 30-year-old patient. Sagittal T1-weighted images obtained before (A) and after (B) gadolinium administration show such extensive enhancement of the subarachnoid space that the enhanced T1-weighted image mimics a T2-weighted sequence. The patient had been treated for astrocytoma 3 years earlier.

Figure 12-39. Cerebrospinal fluid spread of glioblastoma multiforme after biopsy in a 40-year-old patient. Six weeks after stereotactic biopsy, an enhanced coronal T1-weighted image shows the primary right thalamic glioblastoma and extensive, thick dissemination of neoplasm in a pia/subarachnoid space pattern.

Risk Factors for Leptomeningeal Dissemination of Neoplasm

The risk factors for leptomeningeal dissemination differ somewhat for primary CNS and non-CNS neoplasms but are largely related to tumor dedifferentiation and proximity to CSF spaces.

Characteristics of primary CNS neoplasms that correlate highly with a tendency to CSF spread are (1) poor glial fibrillary acidic protein (GFAP) staining, indicating poor differentiation of neoplasm,¹¹⁹ and (2) close proximity to CSF spaces.^{57, 158} Patient risk factors for leptomeningeal dissemination of primary CNS neoplasm include extended survival⁷ and previous operation (see Fig. 12-39).^{6, 8}

In cases of non-CNS neoplasm, prolonged survival^{116, 118, 172} and the presence of other metastatic foci^{14, 116, 156} increase the probability of meningeal dissemination. Dispersion of non-CNS neoplastic cells is likely a multistep process, according to the analysis of the pathways of metastases performed by Viadana and colleagues.¹⁵⁹ This “cascade” phenomenon postulates that spread of the primary tumor occurs to at least one intermediate organ, from which it may disseminate widely.¹⁵⁹ The observation that vertebral body (especially in breast CA),^{14, 156} bone marrow, and liver metastases (especially in lung CA)¹¹⁶ are commonly present in cases of meningeal carcinomatosis lends credence to this predisposition of tumors to first spread to an intervening organ before disseminating widely. The breast, lung, and stomach, in addition to melanoma, are primary sites of solid tumors that tend to metastasize to the leptomeninges.^{71, 72, 118, 161} Hematologic neoplasms such as leukemia and lymphoma are also inclined to CSF spread.⁷²

Mechanisms of Meningeal Neoplastic Dissemination

Dura

The two major mechanisms of spread of neoplasm to the dura are (1) hematogenous dissemination and (2) direct extension.

Hematogenous Spread

One pathway for neoplasm to reach the dura is as a sequela of bone metastases; this route is common in patients with breast CA. Vertebral bone metastases disseminate hematogenously through Batson’s plexus and then to the intracranial dural venous sinuses¹⁵⁶ (Fig. 12-40). For example, dural metastases are as likely as parenchymal brain metastases in cases of disseminated breast CA, reflecting the high incidence of vertebral involvement.¹⁵⁶

Direct Extension

A second route is dural infiltration, with neoplasm extending directly from vertebral or calvarial lesions¹ (Fig. 12-41).

Leptomeninges

The major mechanisms of seeding into the CSF and leptomeninges are also hematogenous spread and direct extension, but these may take a variety of forms.

Hematogenous Spread

There are three main modes by which neoplasm is spread hematogenously to the leptomeninges and CSF.

Figure 12-40. Diagram of the route of hematogenous spread to dura via Batson plexus. (From Fukui MB, Meltzer CC, Kanal E, Smirniotopoulos JG: MR imaging of the meninges: Part 2. Neoplastic disease. *Radiology* 201;605-612, 1996.)

First, the choroid plexus may become seeded hematogenously that results in tumor deposits that are then sloughed into the CSF.^{35, 58, 71, 72} This pathway is presumably more common than is clinically evident. The frequency of choroid metastases is likely to be underestimated on MRI because the normal choroid plexus is irregular in contour. Metastases occur frequently when the choroid plexus is

sectioned at pathologic examination; however, the choroid plexus may not be examined routinely.^{109, 118}

The second hematogenous route is via parenchymal blood vessels in the Virchow-Robin (perivascular spaces) to the pia mater and then into the SAS^{54, 72} (see Fig. 12-2). This mechanism of seeding of the leptomeninges and SAS may result in tumor spread either *to* or *from* the SAS.^{54, 72, 109}

Third, neoplasm may interrupt the thin walls of microscopic vessels in the arachnoid to enter the SAS¹³⁰ (see Fig. 12-2). This pathway of spread occurs more commonly in leukemia and lymphoma than in solid tumors.¹³⁰

Direct Extension

Direct extension, the other major means by which neoplasm gains access to the leptomeninges, can also take one of three forms.

First, parenchymal neoplasm close to CSF borders, such as cortical or subependymal tumor, may shed cells into the CSF^{35, 168} (see Fig. 12-13). Non-CNS neoplasms may induce a fibrous reaction that tends to prevent CSF spread; thus, this pathway may be more common among tumors of CNS origin.^{71, 118}

Second, an overlying dural neoplasm may invade the leptomeninges directly.^{61, 71, 72}

Third, spinal epidural neoplasm can spread contiguously along nerve roots or their lymphatics.^{10, 14, 35, 90, 118, 156} This route of spread is somewhat controversial; some authors assert that the frequency of leptomeningeal carcinomatosis would be greater if this were an important pathway, considering the common occurrence of vertebral metastases.⁷¹

Complications of Meningeal Neoplasms

Once the CSF has been seeded, neoplasm has the potential to disseminate widely from a focus in the leptomeninges, throughout the arachnoid and pia mater, through the perivascular (Virchow-Robin) spaces, or along the sleeves of cranial nerves and spinal nerve roots.⁵⁸ Extension into the perivascular spaces or partial obstruction of the vessel lumen by tumor cells can result in ischemic complications

Figure 12-41. Focal, direct extension of breast carcinoma calvarial metastasis to dura. Coronal enhanced T1-weighted image shows focal dural thickening (arrowheads) and enhancement deep to a calvarial focus of breast carcinoma (see also Fig. 12-21).

Figure 12-42. Carcinomatous encephalitis. *A*, Axial CT of the head obtained before contrast medium shows hypoattenuation in the posterior parietal lobe (*arrowheads*) in a 42-year-old patient who presented with a 4-month history of seizures. *B*, After contrast administration, pial enhancement is minimal (*arrowheads*). The patient was initially thought to have subarachnoid hemorrhage, but autopsy showed extensive adenocarcinoma in the perivascular spaces and meninges, with multiple ischemic foci in the brain and a primary focus in the lung.

of leptomeningeal carcinomatosis (Fig. 12-42).^{118, 161} The term “carcinomatous encephalitis” refers to the rare occurrence of diffuse perivascular (Virchow-Robin space) infiltration resulting in ischemia.^{71, 99} Neoplasm adjacent to the meninges or a small site of meningeal tumor involvement may also provoke a diffuse fibrous response of the meninges.¹¹⁸ Since both the meningeal reaction to neoplasm and the neoplasm itself usually enhance on MRI, this finding is not specific.

Summary

A wide spectrum of non-neoplastic and neoplastic conditions may affect the meninges. MRI with FLAIR sequences or enhanced T1-weighted images is an effective modality for characterizing meningeal pathology. The cardinal MRI findings in meningeal disease are hydrocephalus and smooth or nodular enhancement or signal abnormality of the dura/arachnoid, the pia mater/SAS, and the ependyma of the brain or spine.

Two major patterns of disease are identified: (1) a dura/arachnoid pattern, which follows along the inner table of the calvarium, and (2) a pia mater/SAS pattern, which extends into the sulcal spaces. Nodular disease, in particular, may suggest neoplasm. Meningeal neoplasm may be clinically silent, and false-negative results on CSF cytologic study are common.^{6, 8, 13, 118} The addition of MRI to the clinical data and CSF examination may increase the detection of meningeal involvement and may allow tumor staging.

Understanding the routes of neoplastic spread to the meninges permits identification of imaging features of the primary tumor that predispose to CSF dissemination, such as proximity to the SAS or ventricles. Although there is considerable overlap in the MR appearance of meningeal involvement in various diseases, the pattern and distribution of enhancement may provide guidance for diagnosis, management, and treatment monitoring of disorders affecting the meninges. Correlation of imaging findings with clinical and CSF data is essential to ensure that treatable disease is not overlooked.

Leukoencephalopathies and Demyelinating Disease

Barton Lane

The cerebral (and cerebellar) white matter may be affected by various disease processes. With its ability to detect these alterations in white matter, neuroimaging contributes to the diagnosis and management of these disorders.

It is useful to briefly consider the underlying mechanisms that account for the changes seen on magnetic resonance (MR) images and computed tomography (CT) scans in white matter disease. Demyelinating disorders result in increased water content of the white matter because myelin (rich in solids) is lost, leaving behind more hydrated material. This water is found in extracellular fluid; astrocytes; and, possibly, inflammatory cells. The magnitude of the change depends on the severity of the disease. The abnormally increased water content causes reduced attenuation on CT scans and prolongation of T1 and T2 values on MR scans. In the late stages of demyelination, extreme shrinkage of the affected white matter, accompanied by gross cerebral atrophy, may result.⁶

Cerebral edema, trauma, ischemic lesions, and infection are among the causes of abnormal white matter, as visualized by CT and magnetic resonance imaging (MRI), and may therefore be included in the differential diagnosis of primary myelin disorders. Further, secondary myelin (wallerian) degeneration⁸⁴ occurs when axons are severed or destroyed. This chapter emphasizes primary diseases of white matter or those disorders in which the white matter is the primary focus of the pathologic process.

The classification of white matter disease may seem confusing and arbitrary; it can be undertaken on biochemical, etiologic, clinical, pathologic, or radiologic bases. Some diseases cross nosologic lines; an example is progressive multifocal leukoencephalopathy (PML), in which myelin is destroyed as a result of viral infection, which is in turn secondary to immune compromise. The classification in this chapter is based on that of Waxman.⁹⁵

Normal White Matter

CT Appearance

Normal cerebral white matter in the adult has an x-ray attenuation coefficient 0.5% to 0.8% less than normal gray matter of the cerebral cortex. Average values of 35 to 40 Hounsfield units (HU) for adult human gray matter and 29 to 33 HU for white matter have been derived from clinical

studies. These figures agree with in vitro studies performed on human and primate brains. This small attenuation difference (5 to 7 HU) is detectable on CT as a relative lucency of white matter, as compared with gray matter.

The cause of the lower attenuation in white matter is its myelin content. Myelin accounts for the whitish appearance, the high lipid content, and the relatively low water content of white matter when compared with gray matter (72% versus 82%).^{9, 10} Although white matter is less vascular than gray matter, the low blood content of white matter accounts for only a small fraction of the attenuation difference. Contrast infusion increases the differences in density only slightly. This difference is probably caused by the higher cerebral blood volume in gray versus white matter.

White matter in the infant differs significantly from that in the adult. It is known that complex biochemical and morphologic changes occur in the white matter in utero and throughout the first years of life. Extensive myelination occurs in the first few months after birth and is virtually complete by the end of the second year. Some slower myelination continues throughout childhood and adolescence. Thereafter, the white matter is relatively stable during adulthood.

Immature myelin, compared with the adult form, has a much greater water content. As myelination proceeds in the brain, the white matter loses water and gains lipids and proteolipids until, in the adult, white matter has three times as much lipid as does gray matter. CT density measurements show an average linear increase in brain density from term to 20 weeks, after which the density increases only slightly.⁶³

This high water content of immature myelin has a predictable effect, as seen on CT scans. The white matter in premature and normal full-term infants shows greater lucency (i.e., lesser attenuation) than in adults (Figs. 13-1 and 13-2). This finding must not be mistaken for a pathologic process.^{22, 49, 66} (The thinner neonatal calvaria may also contribute to better gray-white discrimination, since there is less beam-hardening and a better signal-to-noise ratio.)

When the patient is about 6 months of age, the difference in gray-white matter is similar to that in the adult. From ages 2 to 17 years, the normal white matter density values are identical to those of adults.

Constant identifiable changes in white matter in aging human brains have been described. After middle age, the total amount of certain myelin lipids decreases and the

Figure 13-1. Immature myelination in a premature infant. CT scan, obtained at 1 month of age, demonstrates the typical lucency of incompletely myelinated white matter in premature infants. The internal capsules that myelinate first are not visible.

cerebral hemispheres show increased water content. These changes appear as decreased attenuation of the cerebral white matter in CT scans of older patients.⁹ This generalized decrease in white matter density has been correlated with dementia and other clinical symptomatology⁸³; however, the imaging specialist must be cautious when interpreting CT scans in the very aged (as well as the very young) because the observed white matter differences may be a part of the maturation or aging process.

MRI Appearance

On the basis of the neuropathologic differences in the water and lipid content of white matter versus gray matter (as just explained), MRI can be used to exploit these differences in imaging the brain.

T1 and T2 relaxation values in normal white matter are shorter than in gray matter. Thus, on T1-weighted images, white matter is relatively brighter in signal intensity; on T2-weighted images, white matter is less intense, or darker. In general, MRI is superior to CT in delineating differences in white and gray matter, the various gray matter nuclei, and white matter tracts. MRI is more sensitive than CT in demonstrating accurately the extent and distribution of histologically verified central nervous system (CNS) disease, and for that reason MRI should be the imaging procedure of choice in suspected white matter abnormalities. Still, familiarity with the CT findings is important because some patients may undergo CT as the initial imaging procedure or may, for whatever reason, be unable to undergo MRI.

Assessment of myelination patterns in the newborn and in the developing brain by MRI has been well addressed by several MRI investigators.^{2, 5, 20, 34} Myelination of the brain occurs in a more or less orderly fashion, proceeding caudal to rostral, and with more primitive structures myelinating before "newer" ones. Timetables for myelination of specific structures have been published and are useful in assessment of pediatric brain MR images. Generally, nonmyelinated tissue is *hypointense* (darker) on T1-weighted sequences but *hyperintense* (brighter) on T2-weighted sequences; as structures myelinate, they become hyperintense (bright) on T1-weighted sequences but hypointense (dark) on T2-weighted sequences (Figs. 13-3 and 13-4).

Figure 13-2. CT scans of myelin in a normal neonate. The immature myelin with its high water content imparts a generalized lucency to the central white matter. Note especially the discrete border with overlying cortical tissue. The internal capsule, however, having more mature myelination, is not visualized separately.

Figure 13-3. MR images of normal early myelination in a 14-day-old infant. *A*, T1-weighted scan, midsagittal view. Note the hyperintense signal indicating myelination in the midbrain, upper medulla, and central cerebellum. The corpus callosum shows little myelination at this time. *B* and *C*, T1-weighted axial images. Myelination is evident in the posterior limbs of the internal capsule and cerebral peduncles. *D* and *E*, T2-weighted axial images. The medulla and deep white matter of the cerebellum demonstrate hypointensity of early myelination. Supratentorially at the level of the centrum semiovale, there is early myelination of the sensory-motor cortex.

Figure 13-4. Normal myelination pattern in a 21-month-old child. MR images demonstrate almost complete myelination. A, T1-weighted midsagittal image shows the configuration and hyperintensity of the corpus callosum, similar to that of an adult. B and C, T2-weighted axial images. Virtually all myelination is complete, as manifested by hypointensity. The only remaining hyperintense signal is in the terminal myelination zones, in the deep periventricular white matter of the parieto-occipital region.

Diffusion-weighted imaging (DWI) and diffusion tensor techniques are MRI methods that further characterize brain tissue, especially white matter. Diffusion-weighted imaging, although used mostly for imaging of stroke, has been applied to many demyelinating and metabolic brain diseases, including Krabbe's disease and multiple sclerosis (MS).^{31, 78}

Viral and Postviral Demyelination

Among the diseases that may directly involve the white matter are those in which hypersensitivity and immunity play a predominant role. In such cases, the cerebral hypersensitivity reaction causes the observed clinical and pathologic state, whether the initial offending antigen is a virus, foreign protein, or autoantigen. *Acute disseminated encephalomyelitis* (ADEM), or *immune-mediated encephalomyelitis* (IME), affects white matter to a greater or lesser degree and may be identified by CT or MRI. In patients with this condition, the viral agent cannot be detected in the CNS.

Conversely, there are patients with diminished immunity in whom a virus, which normally cannot gain a foothold

in the CNS, propagates there unchecked and results in demyelination; such a disease is PML. Some virus-associated demyelinating conditions are described next.

Acute Disseminated Encephalomyelitis

ADEM has been associated with varicella zoster infections and measles as well as with rubella, influenza, and possibly infectious mononucleosis. The postvaccinal types result from inoculation for rabies, yellow fever, or influenza or from other brain-derived vaccines.⁷⁷ In some subacute forms of ADEM, the onset is slower and the course of the disease is prolonged. Corticosteroid medication may be beneficial in these conditions.⁷¹

The distribution of the encephalomyelitis is predominantly in the white matter, characterized pathologically by lymphocytic and mononuclear perivenous inflammation. The demyelination may be local or diffusely confluent, and variable degrees of edema may be present.

Although low-attenuation lesions in the white matter have been described on CT scans,⁵⁰ MRI is much more

Figure 13-5. Acute disseminated encephalomyelopathy (ADEM). A and B, Non-contrast-enhanced CT scans demonstrate multifocal white matter lucencies, most visible in the basal ganglia bilaterally as well as in the parieto-occipital white matter. C and D, There is no contrast enhancement. The multiplicity of lesions is typical.

sensitive and is the imaging method of choice in demonstrating the lesions of ADEM (Figs. 13-5 and 13-6). T2-weighted MR images are the most sensitive, with asymmetrical white matter foci of hyperintensity. The size and number of lesions are variable. Even gray matter may be involved.

Enhancement with gadolinium may be prominent, either as punctate foci or, less commonly, as ringlike lesions.¹² Corresponding lesions may be also be seen in the spinal cord and less commonly in the optic nerves. An important differential diagnostic consideration is MS, but fortunately the time course of the two diseases differs.⁴¹ MS is relapsing-remitting, whereas ADEM is a monophasic illness.

Another important diagnostic consideration is vasculitis, which may mimic the lesions of ADEM. ADEM usually resolves, and the prognosis for recovery is good.

Progressive Multifocal Leukoencephalopathy

A compromised immune system may predispose to viral replication in the brain, resulting in leukoencephalopathy.

PML is a rare, subacute demyelinating disease caused by replication of polyoma virus in the brain of an individual with immunosuppression, first reported with malignant

Figure 13-6. Acute disseminated encephalomyelopathy (ADEM) in a 52-year-old man with memory loss, apathy, and inflammatory cells in the cerebrospinal fluid. *A* and *B*, Cranial MR T2-weighted axial images show multiple, hyperintense lesions involving the right medial temporal lobe, both cerebral peduncles, and the mesencephalic deep white matter. *C* and *D*, Gadolinium contrast-enhanced, T1-weighted MR images at the same levels show patchy multinodular contrast enhancement within the lesions.

lymphoproliferative disease.^{65, 92} PML has been associated with acquired immunodeficiency syndrome (AIDS) and is now the most frequently encountered predisposing disease.⁴⁷

PML has a characteristic radiographic appearance on CT and MRI scans (Figs. 13-7 to 13-12).^{53, 97} Subcortical foci of demyelination are seen with scalloped lateral borders following the outline of the intact overlying cortex. With CT, the lesions show decreased attenuation; with MRI, they are correspondingly intense on proton-density and T2-weighted images. In my experience, there is a predilection for the parieto-occipital region. The corpus callosum, the internal and external capsules, and the poste-

rior fossa structures are less commonly involved. The disease is progressive, and early minimal lesions can be followed temporally by CT and MRI as they become larger and coalesce.

Mass effect is usually absent on both pathologic and radiologic examinations and radiographically. In rare cases, the lesions are edematous and swollen, making the imaging diagnosis more problematic. Contrast enhancement, which helps to distinguish this disease from toxoplasmosis and other opportunist infections and acute MS, is not usually present. In later stages of the disease, shrinkage of the affected white matter may cause ipsilateral atrophic changes.

Figure 13-7. Progressive multifocal leukoencephalopathy (PML) in a 63-year-old man with worsening right hemiparesis and a lung nodule. On the basis of this CT scan, a left frontal brain biopsy, which was diagnostic of PML, was performed. A large, low-density lesion occupies the entire left centrum semiovale. Other, lower sections showed the lesion extending down into the internal capsule; a second, much smaller lesion was also visible in the right parietal white matter. The clearly defined borders of the lesion, the absence of contrast enhancement, and the lack of mass effect, despite the lesion's considerable extent, are typical of PML.

Figure 13-8. Progressive multifocal leukoencephalopathy (PML), typical pathologic specimen. The patient is a 51-year-old woman with a 7-month history of personality changes, blindness, dementia, and eventual coma. *A* and *B*, Horizontal brain sections obtained at autopsy. Almost the entire right hemispheric white matter has been replaced by a granular necrotic process. A similar process has begun in the left hemisphere. *B*, Close-up view of unfixed right frontal lobe. The typical lesion of PML has destroyed the central white matter and extends across the corpus callosum. Note the spared cortical mantle.

Figure 13-9. Progressive multifocal leukoencephalopathy (PML) associated with acquired immunodeficiency syndrome (AIDS). *A*, This non-contrast-enhanced CT scan, in this patient with rapidly progressive neurologic disease, shows a well-defined area of lucency in the right parieto-occipital white matter extending forward into the external capsule and medially into the splenium of the corpus callosum. Lesser involvement in the opposite occipital lobe is also present. *B*, Postcontrast image at the same level shows nonspecific enhancement of the overlying cortex but none within the white matter lesions. The diagnosis of PML was confirmed by biopsy.

Figure 13-10. Progressive multifocal leukoencephalopathy (PML) in a 56-year-old man with human immunodeficiency virus infection and hemiparesis. *A*, Cranial T2-weighted axial MR image shows a confluent hyperintense white matter lesion adjacent laterally to the right occipital horn. Note the sparing of the overlying gray matter cortex. *B*, Magnetization transfer (MT) postgadolinium-enhanced MR axial image. Note the minimal contrast enhancement, which was not seen on CT or standard T1-weighted MR images.

Figure 13-11. Progressive multifocal leukoencephalopathy (PML) and toxoplasmosis in a 46-year-old man with acquired immunodeficiency syndrome (AIDS). A and B, Proton-density and T2-weighted axial images at the level of the thalami. Bilateral, edematous basal ganglia lesions are typical of toxoplasmosis. Bilateral, deep white matter hyperintense lesions are also seen in both occipital lobes, compatible with a diagnosis of PML. The thalamic lesions enhanced with contrast medium; the occipital lesions did not. C, T2-weighted axial image demonstrates presumed PML of the pons.

Figure 13-12. Progressive multifocal leukoencephalopathy (PML) in a 44-year-old man with chronic lymphocytic leukemia. Cranial T2-weighted axial MR images. A, At the level of the midbrain, there are bilateral temporal white matter lesions, with complete sparing of the overlying cortex. B, Symmetrical, hyperintense cerebellar white matter lesions are seen in the brachium pontis and corpus medullaris. The diagnosis of PML was confirmed by biopsy.

In the appropriate clinical setting, MRI or CT can be of value in confirming the clinical suspicion of PML when radiographic findings are typical. Equally valuable is the exclusion of underlying tumor or abscess.

AIDS-Related Leukoencephalitis

It is now known that the human immunodeficiency virus (HIV) is not only lymphotropic but also neurotropic. It replicates in multinucleated giant cells within the CNS, resulting eventually in demyelination. This demyelination is characterized by negligible edema and a lack of inflammation. Neuroimaging of HIV encephalitis, whether by CT or MRI, tends to lag behind the pathologic involvement. Generalized atrophy is the most common abnormality that is nonspecific. With more severe involvement, CT discloses symmetrical white matter hypodensity, usually seen bifrontally. There is no contrast enhancement or mass effect.

With MRI, there is greater sensitivity, with diffuse increase in signal on T2-weighted and proton-density images (Fig. 13–13). Patchy white matter lesions may become confluent and extensive; this may cause diagnostic confusion with PML, also commonly associated with AIDS.^{60, 70} Patients with PML are usually much more symptomatic, with more rapid deterioration.

Toxic and Traumatic Encephalomyelopathies

Many toxic and traumatic processes may selectively damage or destroy the myelinated portions of the brain. Among the agents implicated are (1) gamma radiation, (2)

various chemotherapeutic agents, (3) heavy metals, (4) chemical toxins, and (5) specific surgical lesions. The demyelination may result from two more agents acting in concert, such as methotrexate therapy combined with cranial irradiation.

Radiation-Induced Demyelination

Radiation to the brain may cause *radiation necrosis* (radionecrosis) or *diffuse leukoencephalopathy*. These two types differ in their clinical course and in their pathologic and radiographic appearance.

Radiation Necrosis

Radiation necrosis is characterized by coagulative destruction of the white matter, accompanied by fibrinoid necrosis of the capillary blood vessels. The lesion is the result of high-dose focal radiation therapy to the brain, usually appearing after a latent period of 4 months to several years. Characteristically, radionecrosis appears on CT scan as abnormal low-density white matter with mass effect and may have a higher density central core that enhances (Fig. 13–14).

MRI is more sensitive and specific than CT and shows prominent white matter edema on T2-weighted and proton-density images. A core of enhancing mass may be present, and the differential diagnosis from recurrent tumor may be difficult. Often the distinction can be made only by positron emission tomography (PET) or by magnetic resonance spectroscopy (MRS) to distinguish the metabolically active tumor from the inactive radiation necrosis. Stereotactic biopsy may be necessary in selected cases.

Figure 13–13. Human immunodeficiency virus encephalitis in a 39-year-old patient with acquired immunodeficiency syndrome (AIDS) and rapidly worsening dementia. A and B, Proton-density and T2-weighted axial MR images show widespread diffuse hyperintensity of the deep cerebral white matter. Not shown is similar involvement of the pons and mesencephalon.

Figure 13-14. Radiation necrosis, contrast-enhanced CT scan. A small, enhancing focus within the right posterior corona radiata is surrounded by white matter lucency. (The right frontal pole encephalomalacia resulted from a previous biopsy establishing the diagnosis of intracranial lymphoma.) The differential diagnosis of the contrast-enhancing lesion includes infection or recurrent tumor. At autopsy, radiation necrosis was found without lymphoma or abscess.

Diffuse Radiation-Induced Leukoencephalopathy

Diffuse radiation-induced leukoencephalopathy is more common than radiation necrosis.^{74, 87} This diffuse leukoencephalopathy may involve all visible cerebral white matter when whole brain irradiation has been given, or it may correspond closely to irradiated volumes after treatment for a solitary brain tumor.

CT scans show diffuse, low-density white matter without contrast enhancement and no mass effect. The surrounding cortical gray matter ribbon is preserved. Correspondingly, MRI shows abnormal signal intensity in the white matter on T2-weighted and proton-density images (Fig. 13-15). The lesions may start as small foci, which then coalesce to become symmetrical. Some of the most symmetrical white matter involvement in any disease category is seen in diffuse radiation-induced leukoencephalopathy.

Patients may have dementia or may have focal neurologic findings, but MRI is so sensitive that the lesions may be discovered incidentally during follow-up examinations of relatively asymptomatic individuals. In some patients, the changes are stable; in others, they may progress. Changes are more severe with advancing age and an increasing radiation dose.

Disseminated Necrotizing Leukoencephalopathy

Disseminated necrotizing leukoencephalopathy (DNL), or *subacute leukoencephalopathy*, closely related to radia-

tion necrosis, is an iatrogenic complication of intensive chemotherapy directed to CNS malignancy.²⁷ Responsible agents appear to be combined whole brain irradiation with chemotherapy, most commonly methotrexate.

DNL has been associated with multiagent chemotherapy without irradiation in such conditions as adult leukemia and bone marrow transplantation for breast cancer.⁹¹ On pathologic examination, the lesions consist of discrete multifocal necrosis disseminated randomly in the white matter and becoming confluent and extensive in extreme cases.

CT and MRI findings are similar to those seen with postradiation encephalopathy (Fig. 13-16). In milder forms, CT and MRI show diffuse symmetrical white matter lesions similar to those seen with radiation alone.^{62, 74} Again, as in radiation-induced injury, the most severe cases lead to swelling with ventricular compression and midline shift and to contrast enhancement.

Mineralizing Microangiopathy

Another sequela of radiation treatment and chemotherapy results in intracerebral calcifications, commonly located in the subcortical zones and basal ganglia, and, less commonly, in the cortex. These findings are usually associated with generalized atrophy and diffuse white matter disease, seen as lucency on CT scans and hyperintensity on MR images. This is one entity in which CT scanning may be more diagnostic, since MRI is relatively insensitive to the calcifications unless gradient techniques are used (Figs. 13-17 and 13-18).

Marchiafava-Bignami Disease

Marchiafava-Bignami disease (MBD), originally described in Italian alcoholic patients, is characterized by toxic demyelination of the corpus callosum and, frequently, by extension to the centrum semiovale.

Pathologically, the myelin loss may be striking and may be accompanied by axonal degeneration. Acute deterioration is common, but survival with little permanent deficit is possible. Both CT and MRI show prominent involvement of the corpus callosum, resulting in lucency on CT scans and hyperintensity on T2-weighted and proton-density MR images (Fig. 13-19). MRI is superior to CT in demonstrating the extracallosal sites of involvement.^{16, 25, 75, 100}

Hypoxic-Ischemic Leukoencephalopathies

The white matter of the brain is susceptible to hypoxic-ischemic events and may be involved even when the insult is systemic and generalized. Thus, a leukoencephalopathy can be the end result of long-standing hypertension or a single hypotensive episode (e.g., perinatal hypoxia).^{8, 11} These and other related disorders are considered in the following sections.

Figure 13-15. Leukoencephalopathy secondary to radiation and intraventricular methotrexate chemotherapy. A and B, Proton-density axial cranial MR image. There is extensive diffuse, confluent white matter hyperintensity.

Figure 13-16. Leukoencephalopathy secondary to multiagent chemotherapy for acute lymphocytic leukemia without radiotherapy. A and B, T2-weighted axial cranial MR images show diffuse, mild hyperintensity in the deep white matter bilaterally. Despite the MR appearance, this patient had minimal neurologic signs and was doing well in school.

Figure 13-17. CT scan shows calcification with leukoencephalopathy (mineralizing microangiopathy). The patient is a 7-year-old girl who, 1 year previously, had received 55 Gy to the posterior fossa for a cerebellar astrocytoma. At the time of the scan, she was asymptomatic. The heavily calcified focus in the right parietotemporal region is typically situated at the interface between the cortex and white matter; the latter is abnormally lucent just medial to the calcification. Similar subtle changes are mirrored in the opposite hemisphere.

Figure 13-18. Diffuse necrotizing leukoencephalopathy (DNL) in a 20-year-old man with acute lymphoblastic leukemia several years after intrathecal methotrexate therapy and craniospinal irradiation. This T2-weighted axial MR image demonstrates widespread demyelination; there also is a focus of T2-weighted hypointensity in the left frontal deep cortex, indicating dystrophic calcification (mineralizing microangiopathy).

Figure 13-19. Marchiafava-Bignami disease. MRI demonstrates callosal and extracallosal demyelination. A, T1-weighted sagittal image of through-and-through demyelination focus in body of corpus callosum. B, T2-weighted axial scan with hyperintensities in corpus callosum as well as bilateral cerebral white matter.

Global Hypoperfusion Syndromes

Prolonged hypoxia with accompanying systemic hypotension and acidosis can cause selective injury to cerebral white matter. Common etiologic factors include drug overdose, cardiac and respiratory arrest, anesthesia accidents, profound hypoglycemia, strangulation, postoperative shock, carbon monoxide poisoning, status epilepticus, and vasospasm from a ruptured aneurysm.¹⁴ Selective cerebral edema, elevated venous pressure, and structural peculiarities in the microvasculature of white matter have been proposed as causes for the apparently greater vulnerability of myelinated brain to hypoxic insults.

The damage to white matter ranges from myelinopathy to patchy or confluent frank necrosis. The severity of the lesion seems to correlate with the degree of systemic metabolic acidosis and systolic hypotension associated with the hypoxia.⁴²

Lesions in cerebral cortex and basal ganglia are often observed in contiguity with the leukoencephalopathy. These changes are especially prominent in arterial boundary watershed zones, which may make differentiation from infarction difficult (Fig. 13–20). The gray matter, however, may be unaffected in the presence of severe white matter damage. Sparing of gray matter is particularly likely in so-called delayed hypoxic encephalopathy, observed in some patients who survive the initial insult and then develop subsequent neurologic signs.

The imaging appearance of global hypoperfusion states is therefore variable.⁴² Symmetrical hypodensity of the white matter and lentiform nuclei has been reported in CT scans of patients after anoxia or cardiac arrest. Diffusion-weighted MRI can be of value in characterizing global cerebral anoxia and hypoxic-ischemic brain injury in neonates.^{1, 98}

Figure 13–21. Hypertensive encephalopathy (reversible posterior leukoencephalopathy syndrome). T2-weighted axial MR scan shows symmetrical hyperintensity of occipital lobe white matter. The patient, a 52-year-old woman, experienced visual changes and acutely elevated blood pressure.

Figure 13–20. Deep watershed infarction mimicking primary leukoencephalopathy. Two CT images demonstrate right-sided white matter lesions, most prominent in the frontal and occipital region but confluent in the corona radiata. This represents ischemic leukoencephalopathy, secondary to acute deep watershed infarction. The CT scan had been normal 1 week previously at the onset of symptoms.

The following topics consider the CT and MRI findings in ischemia-related leukoencephalopathies. Primary gray matter (cortex and basal ganglia) lesions and syndromes are beyond the scope of this chapter and are not included. Even though some overlap exists with toxic encephalopathies, the major causative factor in the examples discussed here is vascular pathology.

Hypertensive Encephalopathy

An encephalopathy may develop in hypertensive patients with a rapidly rising blood pressure. This encephalopathy is caused by vascular alterations, which in turn lead to widespread cerebral edema, parenchymal microinfarcts, and even petechial hemorrhages. CT scans of patients with clinical hypertensive encephalopathy show extensive, symmetrical, well-defined hypodensity in the centrum semiovale, internal and external capsules, and periventricular white matter.^{45, 69, 96} MR images are even more revealing, with T2-weighted and proton-density se-

quences more sensitive for the edema (Figs. 13–21 and 13–22).

Eclampsia

A specialized type of hypertensive disorder occurs in pregnancy, usually in the last trimester. Neurologic complications may include seizures, focal neurologic deficits, and even decreased level of consciousness. Most commonly, the posterior hemispheres are involved, often in a symmetrical fashion. On CT scans, the white matter shows symmetrical decreased density²⁶; on MR images, long repetition time (TR) images show hyperintensity in the deep white matter of the occipital lobes.^{7, 24} In other cases, scattered subcortical white matter lesions may also appear, and even basal ganglia involvement has been reported. Fortunately, with aggressive clinical treatment, most patients recover (Figs. 13–23 and 13–24).

A similar mechanism may explain the *reversible posterior leukoencephalopathy syndrome*, which affects some

Figure 13–22. Hypertensive leukoencephalopathy in an 83-year-old woman with aspiration pneumonia and deteriorating mental status. A and B, Axial MR dual-echo axial images at the level of the lateral ventricles demonstrate extensive, symmetrical white matter edema, with moderately severe mass effect compressing both ventricles and effacing sulci. C, T2-weighted image at the level of the thalami. Edema is widespread and involves temporal and frontal lobes as well. Six months later, these changes were completely reversed.

Figure 13-23. Eclampsia (reversible posterior leukoencephalopathy syndrome). A and B, T2-weighted MR axial images show the predominantly occipital white matter swelling. Cortical and left basal ganglia involvement are present.

patients treated with cyclosporine or combination chemotherapy.^{13, 36}

Figure 13-24. HELLP syndrome (hemolysis, elevated liver enzymes, low platelets), a severe form of eclampsia. Axial CT scan demonstrates bilateral occipital vasogenic edema and a small subcortical hemorrhage.

Binswanger's Disease

Binswanger's disease, or *subcortical arteriosclerotic encephalopathy* (SAE), is another ischemia-related leukoencephalopathy. It is now considered to be a diffuse or multifocal destructive process in the central white matter that results from generalized ischemic or vascular conditions.

Pathologically, the symmetrical and diffuse white matter lesions are associated with severe arteriosclerosis of the small penetrating arteries, which are thickened, hyalinized, stenotic, or even occluded. In most patients, multiple lacunar infarcts are also present in the basal ganglia, thalami, and pons (*état lacunaire*). The lacunar state in white matter (*état criblé*) may be the same disorder or at least a variant thereof.⁸⁹

In affected patients, CT reveals a diffuse, severe, incompletely symmetrical hypodensity of the central white matter, especially prominent in the frontal lobes and the centrum semiovale.^{29, 103} MRI changes are much more striking, consisting of subcortical and periventricular lesions visible on fluid-attenuated inversion recovery (FLAIR), T2-weighted, and proton-density sequences. The areas are irregular, commonly grouped around the frontal and occipital horns, and in the centrum semiovale. Moderate, generalized cerebral atrophy is invariably present, and lacunar infarcts in the basal ganglia and thalami are common.

Although logical proof is lacking in many instances,

since the disease is nonfatal and chronic, often lasting for 10 years or more, sufficient case descriptions confirm that at autopsy some of these patients do have the typical neuropathologic features of SAE.^{48, 89} The radiologic diagnosis of SAE may be suspected if diffuse or confluent hypodensity of the white matter, moderate cerebral atrophy, and lacunar infarcts are seen on CT or MRI scans of a hypertensive patient with clinical features of the disease. An interesting genetically transmitted form of the disease is known as *familial arteriopathic leukoencephalopathy*, or *CADASIL* (cerebral autosomal dominant arteriopathy with strokes, ischemia, and leukoencephalopathy) (Fig. 13–25).²⁸

A milder white matter change may be noted in some elderly individuals.³² These foci of increased MRI signal intensity are located in the immediate periventricular white matter extending from the frontal horns along the bodies of the lateral ventricles and also involving the trigones. This white matter abnormality is smooth and continuous and may be thin to more than a few millimeters thick. This entity appears to be different from ischemic leukoencephalopathy, since it is found in normal individuals, is accentuated with age, and is not necessarily associated with dementia or clinical symptomatology. Lacunar infarcts are not usually present. Rather than demyelination, the most likely explanation for this white

Figure 13–25. Familial arteriopathic leukoencephalopathy in two family members who were nonhypertensive with dementia. Cranial MR images are shown. Cerebral autosomal dominant arteriopathy with strokes, ischemia, and leukoencephalopathy (CADASIL) was confirmed at autopsy. *A* and *B*, Proton-density and T2-weighted axial images of diffuse symmetrical demyelination with cystic components in a 52-year-old man. *C* and *D*, T2-weighted axial MR images demonstrate extensive cribriform hyperintense signal in the basal ganglia and confluent demyelination in the centrum semiovale in a 70-year-old woman.

Figure 13-26. Central pontine myelinolysis (CPM), pathologic specimen. The patient is middle-aged, with chronic alcoholism and progressively impaired mental status. At autopsy, the classic triangular demyelinative lesion of CPM was found.

matter change is an aging process resulting in subependymal accumulation of fluid.

Central Pontine Myelinolysis

Central pontine myelinolysis (CPM) is a syndrome of acute pontine demyelination. Most patients with this disorder have a history of alcoholism associated with hyponatremia and exacerbated by overhydration and administration of diuretic medications. Other etiologic factors include systemic hypotension, cerebral edema, and drug-induced, inappropriate antidiuretic hormone secretion. The typical clinical presentation is a rapidly progressive, pontine-level, neurologic deficit (i.e., quadriparesis and pseudobulbar symptoms) that often progresses to a “locked-in” syn-

drome. Permanent and irreversible neurologic damage may result if appropriate treatment is not instituted early in the course. Partial or full recovery has been reported.⁶⁸

Pathologically, the classic picture is edematous demyelination of the central ventral pons, with characteristic sparing of the tegmentum (Fig. 13-26). The demyelination may extend cephalocaudad from the superior cerebellar peduncle to the inferior olive. It is postulated that either the grid arrangement of descending and crossing tracts in the pons or perhaps its vulnerable vascularity is responsible for the peculiar focality of the lesion.

Although CT scans of patients with clinically apparent CPM may show central pontine radiolucency,⁸⁵ MRI is much more sensitive and is the imaging method of choice. Even on T1-weighted images, a low-signal-intensity lesion in the central pons may be seen (Fig. 13-27); however, T2-weighted images are much more preferable. The classic appearance is a triangle- or trident-shaped, central pontine hyperintensity seen in the axial plane (Fig. 13-28; see Fig. 13-27).

In more severe disease, almost the entire central pons may be involved with only a rim of normal signal around it (see Fig. 13-28). Peripheral contrast enhancement has been reported but is not a prominent imaging feature. The abnormality may regress with clinical treatment, leaving little or no residuum.

The differential diagnosis must include a variety of brain stem lesions, including ADEM, vasculitis, MS, Lyme disease, and, in rare cases, brain stem tumor.^{37, 56} The clinical setting and the central symmetry of the lesion are usually sufficient for the imaging diagnosis of CPM.

Leukodystrophies and Dysmyelinating Disorders

The term *leukodystrophy* includes a heterogeneous group of hereditary diseases characterized by meta-

Figure 13-27. Central pontine myelinolysis (CPM) in a 56-year-old man. A, Midsagittal T1-weighted cranial MR image shows a triangular hypointense lesion in the midpons. B, Axial T2-weighted MR image at the midpontine level. Note the classic trident-shaped hyperintense lesion, characteristic of CPM.

Figure 13-28. Central pontine and extrapontine myelinolysis in a 45-year-old man. *A*, T2-weighted axial MR image through the pons at the level of the brachium pontis shows a symmetric, trident-shaped hyperintense lesion of the pons. *B*, T2-weighted image through the upper pons shows that the lesion is occupying virtually the entire pons, leaving only a rim and a few islands of normal intensity. *C*, T2-weighted axial image at the level of the foramen of Monro demonstrates abnormally increased symmetric signal intensity in the thalami and external capsules bilaterally.

bolic defects that principally affect the CNS myelin sheath. The concept of *dysmyelination* was introduced by Poser to delineate those diseases in which myelin does not form properly, is delayed or arrested in development, or is not maintained. When *demyelination* (myelinoclasia) occurs, normal myelin is destroyed, as in MS.

Included in the leukodystrophies are the following major subtypes:

- Adrenoleukodystrophy
- Metachromatic leukodystrophy
- Globoid cell leukodystrophy (Krabbe's disease)
- Neutral fat (sudanophilic and orthochromatic) leukodystrophy
- Mitochondrial disorders (Leigh's disease, MELAS syndrome, MERRF, Kearns-Sayre syndrome) (see "Mitochondrial Cytopathies" later)
- Aminoacidopathies (maple syrup urine disease, phenylketonuria, Wilson's disease)
- Mucopolysaccharidoses (Hurler's syndrome)
- Megaloencephalic leukodystrophies (Canavan's disease, Alexander's disease)

Adrenoleukodystrophy

Adrenoleukodystrophy (ALD) is a hereditary dysmyelinating disease associated with adrenocortical insufficiency and melanoderma. Its primary clinical manifestation is progressive neurologic dysfunction. The disease, caused by a deficiency of the enzyme acyl-coenzyme A synthetase, is transmitted as an X-linked recessive gene and is therefore almost exclusively confined to males, although a few sporadic cases involving females do occur.

The onset is usually in childhood, with characteristic signs of progressive behavioral aberrations, visual loss, and ataxia; there may be no clinical signs of adrenal hypofunction. The patient can live for several years, but a vegetative state leading to death is the almost inevitable outcome. Rare cases of remission, long-term survival, and response to steroid medications have been reported.^{93, 102} Various subtypes involve multiple enzymatic defects, including adrenomyeloneuropathy, affecting the spinal cord and peripheral nerves, and a neonatal form.

Pathologically, the cerebral lesions are most severe in the parietal, occipital, and posterior temporal white matter,

invariably sparing the overlying cortex. The lesions are confluent and often extend in continuity across the corpus callosum. The fornix, hippocampal commissure, and posterior cingulum are also usually affected. Whereas the disease is symmetrical and widespread posteriorly, frontal involvement is more asymmetrical and variable. Cerebellar white matter lesions are common.

Histopathologically, the white matter lesions of ALD are interesting for their significant inflammatory changes and for the sequential zones of involvement in a caudal-rostral distribution. The frontal advancing zone of demye-

lination is followed closely by a zone of inflammatory response, in turn followed by the largest zone of complete destruction of white matter. ALD is one of the dysmyelinating diseases with a characteristic imaging appearance.^{19, 61, 88}

Lesions demonstrable by CT and MRI correlate closely with the known neuropathologic alterations (Fig. 13–29). MRI is more sensitive than CT and shows earlier changes (Fig. 13–30).⁴³ The typical appearance is symmetrical white matter hyperintensity on T2-weighted images in the parieto-occipital regions, adjacent to the atria of the lateral

Figure 13–29. Adrenoleukodystrophy (ALD). The patient is a 13-year-old boy who had behavior problems since age 7 years and who recently experienced seizures. *A* and *B*, Precontrast CT images show white matter lucency surrounding the occipital horns and trigones of the lateral ventricles. Less severe white matter abnormalities are present bilaterally in the frontal lobes. *C* and *D*, Corresponding postcontrast sections demonstrate the peripheral serpiginous enhancement around the frontal lobe lesions and crossing the rostrum of the corpus callosum. Note the lack of contrast enhancement in the older, “burned out” posterior lesions. (Courtesy of Valley Radiologic Associates of San Jose, Calif.)

Figure 13-30. X-linked classical adrenoleukodystrophy (ALD) in a 5-year-old boy. *A*, Axial proton-density image with typical demyelination of the posterior corpus callosum and contiguous deep parietal white matter. Note also the bilateral corticospinal tract involvement. *B*, Note contrast enhancement of the splenium of the corpus callosum on the coronal T1-weighted image.

ventricles and splenium. These appear as hypointense lesions on T1-weighted images and as lucency on CT images. The overlying gray matter is entirely spared.

With contrast infusion, serpiginous, garland-shaped enhancement may be visible in the anteriormost periphery of the lesions.⁵⁵ This finding may be subtle early in the course of the disease. Mild to moderate ventricular dilatation may result from the damage caused by the disease. If the patient survives for several years, the extensive demyelinated lesions shrink, causing gross central and peripheral atrophy. Contrast enhancement is not seen at this later stage of disease.

ALD may be difficult to diagnose with confidence on MR or CT scans if imaging is performed very early or very late in the disease, and variant appearances have been described with more or less involvement of the frontal lobes. At the usual time of diagnostic workup several weeks to months after the appearance of the first neurologic symptoms, however, the combination of clinical and imaging features should be highly suggestive.

Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD) is the most common of all the familial leukodystrophies. *Metachromatic* refers to the histologic staining characteristic caused by abnormal accumulations of sulfatides in the white matter. Sulfatide excess is caused by a deficiency of the enzyme arylsulfatase.

The disease is subclassified either clinically or biochemically. The clinical groups include (1) infantile, (2) juvenile, (3) late juvenile, and (4) adult forms. The biochemical variants are (1) arylsulfatase A deficiency (classic MLD) and (2) multiple sulfatase deficiencies. Inheritance is autosomal recessive; the diagnosis is confirmed by demon-

stration of absent or low levels of sulfatase in urine, leukocytes, or cultured fibroblasts.

In the most common form of MLD, symptoms begin in the second or third year of life and progress insidiously. Irritability, frequent crying, and anorexia herald the subsequent manifestations of hypotonicity and lack of truncal control. Further deterioration is accompanied by hypertonicity, extensor postural abnormalities, and intellectual decline. In the later stages of the disease, the patient may be blind, spastic, and unresponsive.

At autopsy the surface of the brain appears atrophic, the white matter is shrunken and sclerotic, and the ventricles are dilated. Changes in the peripheral nerve myelin explain the polyneuropathy often noted in MLD.

Although the diagnosis of MLD is usually established by enzymatic assay for arylsulfatase A deficiency or by peripheral nerve biopsy, MRI and CT have proved useful in suggesting the presence of leukodystrophy in early, undiagnosed cases and in excluding other processes, such as hydrocephalus or intracranial masses.

The typical CT appearance of MLD is a symmetrical lucency of the white matter, especially prominent in the centrum semiovale and the corpus callosum (Fig. 13-31).⁹⁴ There is no evidence of inflammation or contrast enhancement, and the cortical gray matter is spared.

MRI shows symmetrical areas of hypointensity on T1-weighted and hyperintensity on T2-weighted images (Fig. 13-32).^{4, 40} Although the lesions are symmetrical, they may be patchy and there may be cerebellar white matter involvement as well. In the later stages, considerable atrophic dilatation of the lateral ventricles appears. Atrophy may be the only finding in late adult onset cases.

Although MLD has one of the more nonspecific appearances of a leukodystrophy, the diagnosis is usually considered from the combination of clinical and imaging appearances and can then be confirmed by a biochemical analysis.

Figure 13-31. A–C, Metachromatic leukodystrophy (MLD) in a 27-year-old woman with adult-onset dementia. Contrast-enhanced CT shows diffuse, symmetrical hypodensity of the white matter involving the frontal lobe and parieto-occipital lobes and internal capsules and generalized cerebral atrophy. Appropriate laboratory investigation confirmed the diagnosis of MLD as well as the carrier state in numerous family members.

Globoid Cell Leukodystrophy

Globoid cell leukodystrophy (GLD), or *Krabbe's disease* (globoid body leukodystrophy), is a rare dysmyelinating disorder that is inherited as an autosomal recessive gene.

The clinical course of the disease may closely mimic that of MLD, with irritability and hypotonicity progressing to spasticity, myoclonus, and seizures. Unlike MLD, the onset of symptoms is usually earlier (<6 months of age), and the duration of the illness is shorter. Peripheral neuropathy is prominent in both diseases, a feature not present in most other cerebral lipidoses.

The deficient enzyme in GLD is β -galactocerebrosidase. This deficiency results in excessive accumulation of galactocerebrosides in myelin, found in the so-called globoid cells that are characteristic of the disease.

At autopsy, the brain of a GLD victim is shrunken

because of the diffuse central myelin abnormality. The entire cerebral white matter, including the centrum semiovale, internal capsule, pons, and cerebellum, is firm, rubbery, and grayish, although areas of cystic softening may be present within. The subcortical U-shaped fibers and gray matter are unaffected. In the earlier stages of the disease, the white matter lesions would presumably be less significant. The histologic picture is dominated by the presence of globoid cells and complete myelin destruction with loss of oligodendroglia.

The CT findings in GLD range from white matter lucency to diffuse cerebral atrophy (Fig. 13-33).^{3, 44} Well-defined and symmetrical decreased attenuation in the central white matter may be especially prominent in the frontal periventricular region and in the centrum semiovale.

This appearance is much more characteristic of the disease if accompanied by increased density of the thalami,

Figure 13-32. Metachromatic leukodystrophy (MLD) in a 6-year-old boy. A and B, Cranial MR axial proton-density images show severe demyelination involving the deep white matter of both hemispheres with well-defined borders at the subcortical U-fiber junction. The corpus callosum and internal capsules retain some normal hypointense myelin signal. C, Axial T2-weighted MR image at the level of the medulla depicts significant demyelination.

caudate nuclei, and cerebellar cortex. MRI shows prolongation of T2-weighted signal in the deep white matter and thalamic and cerebellar white matter hyperintensity (Fig. 13-34).¹⁸ Contrast enhancement has not been demonstrated. In later stages of the disease, cerebral atrophy may be the predominant imaging feature.

Sudanophilic (Neutral Fat and Orthochromatic) Leukodystrophies

The sudanophilic (neutral fat and orthochromatic) leukodystrophies are difficult to classify. All cases show the accumulation of liberated sudanophilic myelin breakdown products. Several diseases of both sporadic and familial origin may lead to this end. The continuing advances in neurochemistry and neuropathology have served to separate and reclassify some of the entities. It is hoped that, eventually, the neutral fat leukodystrophies will be more accu-

rately characterized. Of these, *Pelizaeus-Merzbacher disease* has been studied extensively, and its imaging features are discussed here. A remaining, less homogeneous group of sudanophilic leukodystrophies is poorly understood and is considered briefly.

Pelizaeus-Merzbacher Disease

Pelizaeus-Merzbacher (PM) disease is a rare familial leukodystrophy in which the affected child or infant shows progressive signs of neurologic dysfunction similar to the signs of MLD or GLD. Ataxia, hyperreflexia, seizures, and mental deterioration eventually result in death.

The laboratory examination is only of limited value and mainly serves to exclude MLD and GLD, since enzyme assays are normal. The definitive diagnosis rests on histologic examination of the affected brain. In PM disease, there is extensive and severe demyelination, with a peculiar, unique, patchy, tigroid appearance. Sudanophilic

Figure 13-33. Globoid cell leukodystrophy (GLD), or Krabbe's disease, in a 3-month-old girl. Two representative CT sections disclose relative density of the cerebellum, thalami, and periventricular regions. Attenuation measurements of these regions confirm a slightly higher density than in the normal cortex. The remainder of the brain shows uniform attenuation without white matter lucency. This is a representative appearance for early GLD, with later scans usually showing minimal white matter changes but severe cortical atrophy.

Figure 13-34. Globoid cell leukodystrophy (Krabbe's disease) in a 5-month-old infant with total body spasticity and high levels of protein in the cerebrospinal fluid. T2-weighted axial MR images. *A*, Abnormal high intensity cerebellar white matter changes. *B*, There is both white matter generalized hyperintensity as well as early T2 hyperintensity in the deep gray matter nuclei (lenticular nuclei, thalami).

breakdown products are present, but inflammation and metachromasia are absent.

The CT appearance of PM disease is nonspecific, with low density in the central white matter and with variable degrees of white matter atrophy. This pattern is diagnostic for a leukodystrophy but is not distinguishable from MLD or GLD by CT alone. On MR images, however, the predominant appearance is lack of myelination without definite evidence of white matter destruction (Fig. 13–35).^{39, 64} Therefore, the brain retains the appearance of a newborn with distinct absence of myelination. Barkovich and colleagues suggest that this absence of myelination is specific for PM disease.⁵ Because CT scans may be normal in early stages,⁸² MRI is recommended as the imaging modality of choice whenever this or other leukodystrophies are suspected.

Cockayne's Syndrome

Cockayne's syndrome is a complex, hereditary, autosomal recessive demyelinating disorder with clinical features of dwarfism, microcephaly, retinal atrophy, deafness, and

progeria (accelerated aging). Basal ganglia calcifications are a known neuropathologic feature of Cockayne's syndrome and can be detected on CT scans. The few MRI reports suggest that the changes are similar to those in PM disease, with the added feature of calcification in the basal ganglia manifesting as decreased signal intensity (Fig. 13–36). The combination of demyelination and basal ganglia calcification may therefore be helpful in the imaging of this entity.

Spongiform Encephalopathy (Canavan's Disease)

Familial spongy degeneration of the CNS (Canavan's disease) is a well-documented disease affecting infants of Ashkenazi Jewish extraction, transmitted as an autosomal recessive trait. Symptoms usually begin at 1 to 3 months of age, and the patient usually dies before the age of 4.

The infants have severe motor and mental deterioration, accompanied by hypotonia, decorticate posturing, and blindness. Progressive megalencephaly caused by enlarge-

Figure 13–35. Pelizaeus-Merzbacher disease (sudanophilic leukodystrophy) in a 1-year-old with marked retardation, abnormal eye movements, and hypotonia. Cranial MR images at age 1 year. *A* and *B*, Axial T2-weighted MR images. Profound hypomyelination. Note the complete absence of myelination in the internal capsule, corpus callosum, and hemispheric white matter. *C*, Mid-sagittal T1-weighted image. The corpus callosum is notably underdeveloped, and a normal, hyperintense myelin signal is absent.

Figure 13-36. Cockayne's disease in an 11-year-old boy. *A*, T1-weighted coronal MR image demonstrates the prominent basal ganglia hyperintensity, presumably T1 shortening caused by extensive calcification. *B*, T2-weighted axial MR image, with the findings of atrophy, generalized demyelination, and signal dropout in basal ganglia from calcifications.

ment of the brain is an important differential diagnostic feature, since there are few other leukodystrophies (e.g., fibrinoid leukodystrophy, or *Alexander's disease*) in which macrocephaly is found.

The enzymatic defect in Canavan's disease is a deficiency of *N*-aspartoacylase, and the disease is classified as a metabolic disorder.

Widespread sponginess of the cerebral myelin, more pronounced in the outer zone of white matter and also affecting the subcortical U-shaped fibers and deep cortical layers, is noted pathologically. No abnormal myelin-breakdown products, globoid cells, or inflammatory changes are present.

The edematous sponginess of the white matter causes a characteristically low radiographic attenuation on CT so that it stands out in relief from the relatively unaffected gray matter (Fig. 13-37). A similar finding on MR images is extremely widespread and symmetrical low intensity on T1-weighted images, and even more prominent high signal on T2-weighted sequences.⁵⁴ Canavan's disease shows some of the most extensive white matter abnormalities, and in a child with progressive megalencephaly this can be almost pathognomonic of the disease. In very late stages, atrophic dilatation is seen, but the white matter abnormality remains. MRI also shows involvement of brain stem and cerebellum, which is difficult to identify with CT.

Fibrinoid Leukodystrophy (*Alexander's Disease*)

Alexander's disease, a very rare sporadic dysmyelinating disease, is a form of spongy sclerosis, similar to spongi-

form encephalopathy (Canavan's disease), in that there is megalencephaly. The distinguishing feature of fibrinoid leukodystrophy is the histologic feature of fibrinoid astroglia changes, the so-called Rosenthal fibers. The demyelination involves almost the entire cerebral white matter.

Changes on CT and MR images are widespread but have a predilection for the frontal lobes, which may help to distinguish the entity from Canavan's disease.⁷⁹ In addition, significant cystic change is a late feature in the frontal white matter. Contrast enhancement is rare but has been reported³⁵ (Fig. 13-38). Atrophy is notable in later stages.

Miscellaneous Neurodegenerative Disorders

Various rare hereditary and spontaneous neurodegenerative diseases may cause pathologic white matter changes that are visible on MR and CT scans.³³ A brief review of some of the more important entities follows.

Gangliosidoses

Tay-Sachs disease (GM₂ gangliosidosis) is associated with a form of dysmyelination. The loss of myelin cannot be accounted for solely on the basis of secondary wallerian degeneration. There is an abnormality of myelin sphingolipid metabolism, even though Tay-Sach's disease is classified not as leukodystrophy but as a lipidosis.

Figure 13-37. Spongiform encephalopathy (Canavan's disease). *A* and *B*, CT scans of a 2½-year-old boy with progressive neurologic deterioration and an enlarging head. There is diffuse, symmetrical, generalized lucency of the white matter. *C* and *D*, A repeated CT scan performed 2 years later, when the patient was 4½ years old and in a vegetative state. Significant ventricular dilatation has supervened. The white matter has become shrunken, resulting in central cerebral atrophy. At this final stage of the disease, the CT appearance is nonspecific. (A–D, From Moss AA, Goldberg I [eds]: *Computed Tomography, Ultrasound, and X-ray: An Integrated Approach*. San Francisco, University of California, San Francisco, Department of Radiology, 1980.)

Macrocephaly and diminished attenuation of the entire cerebral white matter have been reported on CT scans in patients with GM₁ and GM₂ gangliosidoses.⁴

With MRI, deep white matter demyelination may be prominent; thalami may show changes consistent with calcification. No abnormal contrast enhancement is described (Fig. 13-39).

Mitochondrial Cytopathies³⁸

Leigh's disease (subacute necrotizing encephalomyelopathy) is a rare, inherited disorder in which multiple biochemical defects are found. The most striking neuropathologic change is symmetrical vacuolation of the basal ganglia, the brain stem, the cortex, and, to a lesser degree,

Figure 13-38. Fibrinoid leukodystrophy (Alexander's disease), early stage. This child was 7 months old at the time of her first CT scan; she had been in good health until 5 months of age, at which time left focal seizures began, associated with occasional absence spells and generalized lethargy. *A*, Initial CT scan with paradoxically increased density of the medial frontal white matter. *B* and *C*, Significant contrast enhancement in the basal ganglia, frontal white matter, and periventricular brain substance. The external capsule is hyperlucent. This unusual pattern of enhancement is identical to that reported in a biopsy-proven case of fibrinoid leukodystrophy. *D* and *E*, Follow-up CT study 8 months later, during which time the child regressed neurologically and her seizures became refractory to treatment. Contrast-enhanced sections document significant cerebral atrophy in the interim, with less contrast enhancement.

Figure 13-39. Tay-Sachs disease (hexosaminidase deficiency) in a 3-year-old girl with megalencephaly. A, T1-weighted sagittal MR image shows generalized white matter hypoattenuation and extreme hypogenesis of the corpus callosum (a nonspecific finding). B, T2-weighted axial MR shows extreme demyelination of virtually all white matter as well as characteristic T2 prolongation in thalami and lenticular nuclei.

the white matter. Low attenuation in the basal ganglia, brain stem, or central white matter may be seen on CT scans but is much better delineated on T2-weighted MR images (Fig. 13-40).^{15, 17, 86} The most characteristic foci of demyelination are in the lentiform nuclei, the cerebral peduncles, the periaqueductal gray matter, the pons, and the medulla. Contrast enhancement may be seen in the acute stages.

Other mitochondrial cytopathies that have shown abnor-

malities on imaging are *MELAS syndrome* (mitochondrial myopathy, encephalopathy, lactic acidosis, and strokes), *MERRF* (myoclonic epilepsy with ragged red fibers), and *Kearns-Sayre syndrome* (Figs. 13-41 and 13-42).^{73, 99}

Aminoacidopathies

Aminoacidopathies constitute another class of neurodegenerative disorders. Heritable disorders of amino acid

Figure 13-40. Leigh's disease (subacute necrotizing encephalomyelopathy) in a 10-year-old girl with developmental delay and slow neurologic deterioration. A and B, Initial MR scans. C and D, Follow-up scan 3 years later. A, T2-weighted axial MR image at the level of the midbrain. Hyperintensity of the entire mesencephalic tectum is visible, with lesser involvement of the cerebral peduncles. B, Postgadolinium-enhanced, T1-weighted image at the same level demonstrates symmetrical enhancement just anterior to the aqueduct.

Illustration continued on following page

Figure 13-40. *Continued.* C, T2-weighted axial image at the midbrain level. The previously seen hyperintensities have resolved almost completely, leaving only small periaqueductal foci. D, There is residual persistent hyperintensity in the putamina bilaterally.

Figure 13-41. Mitochondrial depletion syndrome in an 8-month-old boy with hypoglycemia, liver failure, and pancreatic insufficiency. A and B, Cranial MR axial T2-weighted images. There is hyperintensity of virtually the entire cerebral white matter, including internal and external capsules, compatible with severe hypomyelination and demyelination.

Figure 13-42. Myopathic carnitine deficiency in a 10-year-old boy with myopathy. Non-contrast-enhanced CT scans show diffuse, widespread, symmetrical lucency of the white matter, suggestive of demyelination.

metabolism may be accompanied by neurologic dysfunction, ranging from mild to severe, acute or chronic.

Some affected infants die of edema brought on by hyperammonemia or anoxia; others have been shown at autopsy to have spongy degeneration of the white matter, demyelination, or hypomyelination.

The more well-known aminoacidopathies include maple syrup urine disease (MSUD), phenylketonuria, the ketotic hyperglycinemias, urea cycle enzyme errors (ornithine transcarbamylase deficiency or citrullinemia), and nonketotic hyperglycinemias. More than 50 subtypes have been described. Depending on the time of imaging, an affected child with one of these aminoacidopathies may show cerebral edema, hypomyelination, or diffuse white matter atrophy (Fig. 13-43).^{6, 51} A characteristic diagnostic feature is the demonstration of white matter edema in the neonatal period, since this excludes most classic leukodystrophies.

Wilson's Disease

Wilson's disease is a rare autosomal recessive disorder of copper metabolism. Although basal ganglia are predominantly affected, white matter tract abnormalities have been routinely characterized by MRI.⁹⁰

Mucopolysaccharidoses

Six well-recognized syndromes are caused by enzyme defects resulting in accumulation of glycosaminoglycans in many organs. *Hurler's syndrome* is the prototype. Although demyelination is not a prominent neuropathologic feature, diffuse white matter changes simulating demyelination have been reported (Fig. 13-44).^{40, 58}

Multiple Sclerosis

The most common demyelinating disease seen in adult neurologic practice is MS. Clinically, it may present in acute, chronic, or relapsing forms. The common neurologic signs are optic neuritis, paralysis, numbness, ataxia, and tremor. Repeated remissions and exacerbations are characteristic, and the average duration of disease is many years.^{67, 95}

The gross pathologic features of MS have been well documented over many decades. The in vivo demonstration of demyelinated plaques was first made possible with the advent of CT, but MRI is clearly the imaging method of choice, with superior sensitivity, specificity, and characterization of the disease process.^{72, 76} In many studies, MRI not only is the most accurate imaging method but also is even more sensitive than other nonimaging tests such as oligoclonal bands, somatosensory evoked potentials, and visual evoked potentials.⁸⁰

The sensitivity of MRI has been as high as 85% in patients with clinically definite MS, and the figure is probably even higher if serial studies are performed.⁵⁹ CT, however, has probably less than half the sensitivity of MRI; nonetheless, a brief description of CT abnormalities is in order, if only for historical interest.

Three CT features are typical of MS:

1. Most characteristic is focal decreased attenuation in the periventricular white matter.
2. Another type of focal abnormality in CT scans of MS is contrast-enhancing plaque. These enhancing lesions have been shown to correspond to the acute phase of demyelination, and the blood-barrier breakdown resolves within a few weeks (Fig. 13-45).⁵⁷ The contrast enhancement may be ameliorated or abolished by the administration of corticosteroids, although the long-term

Figure 13-43. Maple syrup urine disease (MSUD) in a 10-month-old boy with feeding difficulties and developmental delay. When admitted, he was obtunded and his urine smelled faintly of maple syrup. A-C, Three representative sections from the unenhanced CT scan show diffuse, moderately low density of the cerebral white matter. Mild, diffuse cerebral atrophy is apparent on all sections. Lucency of the temporal lobe (A), the internal capsule (B), and the splenium of the corpus callosum (C) is prominent.

Figure 13-44. Mucopolysaccharidosis (Hurler's syndrome) in a 7-year-old girl with mild macrocephaly. CT scan demonstrates the multiple periventricular cysts, characteristic of this disease, as well as more subtle generalized white matter hypodensity. Unusual skull defects with brain herniations are also shown.

Figure 13-45. Multiple sclerosis, acute phase, in a 19-year-old woman with extremity numbness, difficulty in walking, blurred vision, and slurred speech. A–C, Precontrast CT sections are abnormal, with diffuse, patchy hypodensity of the white matter.

Illustration continued on following page

Figure 13-45. Continued. D-F, Corresponding sections after administration of intravenous contrast. There is prominent patchy enhancement of the periventricular white matter bilaterally. Occasionally, as in this case, a few contrast-enhancing plaques may be found in the cerebral cortex, but the periventricular lesions predominate.

Figure 13-46. Multiple sclerosis in 50-year-old woman with previous optic neuritis and relapsing-remitting symptoms. *A*, T2-weighted cranial MR axial image demonstrates several deep white matter plaques and periventricular lesions. *B* and *C*, Proton-density axial images. The periventricular and corpus callosum lesions are visualized more clearly on the proton-density image.

course of the disease does not appear to be altered by this regimen.

3. A less common CT finding in MS is cerebral atrophy, caused by large-scale white matter shrinkage. This results in generalized ventricular and sulcal dilatation.

The foregoing discussion notwithstanding, MRI is the imaging method of choice in cases of suspected MS of the brain and spinal cord. The emphasis is not only on supporting the diagnosis of MS but on the fact that MRI is effective in differentiating MS from other processes, such as slowly growing tumors, brain stem vascular malformations, and vasculitis. The most widely used sequences for detection of MS are the T2-weighted and proton-density sequences. These are rapidly being supplemented by fast spin-echo imaging. Other techniques that may prove to be extremely useful are magnetization transfer; FLAIR; and, possibly, high-dose contrast-enhancement schemes.²¹ Although magnetic resonance spectroscopy is beyond the scope of this chapter, it is evident that it is a powerful technique for the study of MS and other white matter diseases.²³

On standard T2-weighted sequences, MS plaques appear as high-intensity lesions, usually ovoid, elongated, or round. The proton-density and FLAIR scans are very useful because high-signal plaques adjacent to ependymal surfaces may be obscured by high-signal cerebrospinal fluid on standard T2-weighted images (Figs. 13-46 to 13-49).⁸¹

In general, T1-weighted images are much less sensitive, but it is noteworthy that chronic plaques of MS are often

Figure 13-47. Multiple sclerosis (MS), as shown on a fluid-attenuated inversion recovery (FLAIR) MR image; the patient is a 36-year-old woman with relapsing-remitting MS. Note the conspicuity of the numerous bilateral periventricular white matter lesions.

Figure 13-48. Multiple sclerosis (MS). Fluid-attenuated inversion recovery (FLAIR) parasagittal MR image depicts the extensive demyelinated plaques of progressive MS.

well shown, especially in the corpus callosum, on T1-weighted sequences, appearing as low-signal lesions surrounded by a very thin halo of mildly increased signal intensity (Fig. 13-50). Hemorrhage is not seen in MS lesions; edema and mass effect are distinctly uncommon (see later).

The most characteristic diagnostic feature of MS plaques on MR images is not their signal intensity but their anatomic distribution. There is a predilection for periventricular distribution and ependymal surfaces, especially along the occipital horns and, to a lesser degree, the frontal horns. If not pathognomonic, corpus callosum lesions are so characteristic of MS as to be almost specific.⁸¹ Other MS sites commonly affected are the corona radiata, internal capsule, and centrum semiovale. In the posterior fossa, MS plaques are quite common, with a predilection for the surface of the pons, especially near the fifth cranial nerve entry zone, the middle cerebral peduncle (brachium pontis), the floor of the fourth ventricle, and the colliculi.

Contrast enhancement is an important part of MRI technique.³⁰ It is known that acute lesions of MS are accompanied by transient breakdown of the blood-brain barrier, which may be demonstrated with use of gadolinium contrast enhancement. While T1-weighted images are the standard practice, magnetization transfer may show greater detectability of these lesions because of its background suppression (Fig. 13-51; see Fig. 13-49).²¹ Serial studies have demonstrated that contrast enhancement in acute lesions of MS may persist for 6 to 8 weeks after acute demyelination.⁴⁶ The enhancement may be punctate, nodular, or ringlike. In rare cases, there may be single or multiple large foci of MS with mass effect and significant contrast enhancement simulating a tumor (Fig. 13-52).^{52, 101}

Although many cases of MS have these characteristic imaging features, rendering differential diagnosis relatively unimportant, MS lesions may occur anywhere in the CNS, including the cortex and other gray matter nuclei.

The lesions may be few or may be present in otherwise uncharacteristic locations. A differential diagnosis in these

Figure 13-49. MRI features in a 32-year-old woman with spinal and cerebral multiple sclerosis (MS). *A*, Parasagittal fluid-attenuated inversion recovery (FLAIR) sequence. Numerous hyperintense plaques are clustered on the inferior surface of the corpus callosum, highly correlated with the diagnosis of MS. *B*, Contrast-enhanced, T1-weighted, magnetization-transfer coronal image; two enhancing plaques are visible, indicating active demyelination: one in the corona radiata, the other in the brachium pontis. *C*, Sagittal T2-weighted, fast spin-echo MRI of the cervical spinal cord. Numerous plaques are visible, some with evident swelling (edema). *D*, Fat-suppressed, contrast-enhanced image at the same level as in *C*; one of the lesions has ringlike enhancement.

Figure 13-50. Multiple sclerosis (MS) in 29-year-old woman with severe relapsing-remitting symptomatology, cranial MR images. *A*, Parasagittal T1-weighted image, with multiple callosal hypointense plaques. *B* and *C*, Transaxial T2-weighted images at the level of the pons. Multiple scattered hyperintense plaques of MS, bordering predominantly on the fourth ventricle or pontine surface. *C*, Lesions are grouped bilaterally around the fifth cranial nerve entry zone.

Figure 13-51. Multiple sclerosis (MS) in 37-year-old woman presenting with thoracic myelopathy. *A* and *B*, Cranial T2-weighted axial MR images show multiple, hyperintense plaques distributed bilaterally in the centrum semiovale and periventricular regions and especially grouped around the trigones. Note especially the characteristic corpus callosum lesions.

Figure 13-51. *Continued.* C, Postgadolinium-enhanced, T1-weighted axial image, with several enhancing plaques in the deep white matter. D, Postcontrast magnetization transfer (MT) image demonstrates more conspicuous enhancement of additional lesions than the standard T1-weighted sequence. E, Postcontrast midsagittal MR image of the cervicothoracic cord. There are two typical contrast-enhancing MS plaques: one in the anterior cervical cord and one in the posterior thoracic cord at the T2 level. (Incidentally visible is a moderate C5-6 disk protrusion.) Despite the multiple intracranial enhancing MS lesions, this patient had only spinal cord symptomatology.

cases must include demyelination secondary to ADEM, vasculitis, Lyme disease, sarcoidosis, ischemic disease, and, in rare cases, tumors.

As previously described, multiple ischemic white matter foci are usually seen in older patients, are associated with cardiovascular risk factors, are not located in the immediate periventricular white matter in most cases, and rarely involve the corpus callosum. Also, infratentorial ischemic lesions tend to have a different distribution than does MS in the pons and cerebellum. Despite all of these clues, some MR images are indeterminate, and the final diagnosis must await clinical confirmation or serial studies.

Spinal Cord Multiple Sclerosis

Some of the false-negative MRI diagnoses of MS are attributable to cases with only spinal cord involvement.

The spinal cord is much more of a challenge in MRI diagnosis, but newer techniques are yielding more rapid and detailed examinations of such cord lesions. These include multiarray receiver coils, fast spin-echo imaging, and the FLAIR sequence. Reports suggest that cord lesions may be detected in a majority of MS patients using such techniques. Characteristically, the cord lesions of MS appear as high signal intensity on T2-weighted sequences, with the cervical cord involved about twice as often as the thoracic cord. The lesions range from a few millimeters to extension over one or more vertebral segments (Fig. 13-53; see Figs. 13-49 and 13-51).

The most common location is lateral and posterior in the cord, but MS may involve both gray and white matter and may occupy the entire transverse diameter. Swelling of the cord is reported in a minority of cases, with diminished signal intensity on T1-weighted images sometimes

Figure 13-52. Demyelinating disease presenting as a mass. *A*, T2-weighted cranial MR axial image. There is a hyperintense masslike lesion in the left parieto-occipital lobe, surrounded by edema. A few scattered periventricular and deep white matter lesions are also visible bilaterally. *B*, Postgadolinium-enhanced, T1-weighted coronal MR image. Incomplete ringlike enhancement outlines the lesion. Biopsy showed nonspecific demyelination. Follow-up MR several months later showed almost complete spontaneous resolution of this mass. (From Jordan JE, Lane B: MRI characteristics of demyelinating disease mimicking brain tumor. *Appl Radiol*, December 1992, pp 36-38.)

Figure 13-53. Multiple sclerosis (MS) in a 26-year-old woman with myelopathy. *A*, Fast spin-echo, midsagittal T2-weighted cervicothoracic MR image shows extensive, high-intensity demyelination involving the cervical and thoracic spinal cord. The cord appears mildly swollen. *B*, Axial T1-weighted cervical cord MR image at the C2-3 level. The spinal cord appears mildly enlarged. *C*, Postgadolinium-enhanced, T1-weighted MR image at the C2-3 level shows extensive plaque enhancement in the posterior spinal cord. The clinical diagnosis is MS.

visible. Gadolinium enhancement parallels that of MS brain lesions.

The differential diagnosis includes transverse myelitis, other inflammations, and intrinsic cord tumor. The final diagnosis is accomplished, preferably, by serial imaging studies and clinical correlation rather than by biopsy.

The Orbit

Jon Mark Fergenson, Neal Mandell,
James J. Abrahams

Magnetic resonance imaging (MRI) and computed tomography (CT) have revolutionized diagnostic imaging of the orbit and its contents. With its superb soft tissue contrast and ability to image in multiple planes, MRI provides excellent rendering of the orbital anatomy. CT also shows the soft tissues within the orbit very well and is best at displaying anatomy and pathology of the bony orbit.

The fine structures within the orbit require more attention to imaging protocol than many other regions of the body to ensure optimal diagnostic information.

This chapter discusses technique for the more commonly used imaging issues, presents an overview of pertinent anatomy, and touches on a cross-section of orbital pathology, including some familiar and some unusual lesions.

Anatomy

The anatomy of the orbit consists of a bony cavity within which the globe, muscle cone, optic nerve-sheath complex, lacrimal apparatus, and various vascular and nerve structures are packed into a cushion of fat.

The bony orbit is a conical structure that consists of the orbital plate of the frontal bone, the maxilla, the greater and lesser wings of the sphenoid bone, the ethmoid bone, and the lacrimal bone. The inferior and medial walls are quite thin and prone to fracture. The medial wall is named the lamina papyracea, in recognition of its paper-thin nature. Multiple foramina transmit vessels and nerves. The most prominent among these include the superior and inferior orbital fissures, the optic canal, the infraorbital and supraorbital foramina, and the lacrimal duct foramen. Other tiny foraminal spaces are not usually appreciated in imaging because of their size. The contents of the major foramina are listed in Box 14-1.

Box 14-1. Major Foramina of the Orbit

Optic Canal

Optic nerve
Ophthalmic artery

Superior Orbital Fissure

III, IV, VI, V₁ cranial nerves
Lacrimal and frontal nerves
Superior and inferior ophthalmic veins

Inferior Orbital Fissure

V₂ cranial nerve
Infraorbital vessels, zygomatic nerve

The muscle cone consists of seven extraocular muscles: the superior, medial, lateral, and inferior recti as well as the superior and inferior obliques, and the levator palpebrae superioris. All but the inferior oblique muscle originate at the orbital apex at Zinn's ring and pass anteriorly to form tendinous attachments to the globe. The inferior oblique muscle originates on the inferomedial aspect of the orbit and passes in a somewhat lateral course to attach to the posterolateral aspect of the globe. The cone of the muscle has been designated a relative boundary or demarcation in addressing the position of several pathologic processes, with the orbit divided into *intraconal* and *extraconal* spaces. In general, processes involving the intraconal space require surgical attention, whereas extraconal processes are often amenable to medical management.

The globe is approximately spherical, with only a few readily visualized structures: the cornea, lens, anterior chambers, vitreous, and the retina-sclera-choroid complex. None of the conventional imaging modalities is able to visualize the retina from the choroid separately in the healthy patient. When an intervening process does occur, it causes separation of these thin membranes.

Proptosis is evaluated by axial scanning, with a line connecting the lateral orbital walls at the level of the lens and with the imaging specialist measuring from that line to the anterior aspect of the globe.³¹ This measurement should not exceed 21 mm.³¹

The optic nerve-sheath complex consists of the optic nerve, its surrounding meningeal sheath, and the cerebrospinal fluid (CSF), which separates them. The sheath extends from the optic canal to the globe. The normal diameter of the nerve is up to 4 mm. The diameter of the complex may vary from 4 to 6 mm. The amount of visualized subarachnoid fluid is also variable.

Occasionally, the presence of CSF makes it possible to determine whether a tumor arises from the sheath or from the nerve itself. Tumors arising from the sheath, such as meningiomas, form a "tram track" appearance in which the outer layer is thickened but remains separated from the normal-sized nerve by a layer of fluid. Because the nerve takes a sigmoid course from apex to globe, coronal imaging is essential for assessing the optic nerve-sheath complex.

The lacrimal apparatus consists of the lacrimal gland, its secretory duct, and the ductal system, which drains these secretions into the nasal cavity. The gland lies in the superolateral aspect of the orbit. The draining ductal system lies near the medial canthus and consists of the superior and inferior puncta, their associated ducts, the lacrimal sac, lacrimal duct, and the valve of Hasner, a draining orifice inferolateral to the inferior nasal turbinate.

The anterior border of the orbit is formed by the orbital

Figure 14-1. A, Coronal CT scan: normal anatomy. Lateral rectus (a), superior rectus (b), medial rectus (c), superior oblique (d), levator palpebrae superioris (e), lacrimal gland (f), inferior oblique (g). B, Medial rectus (a), superior oblique (b), ophthalmic artery (c), superior rectus/levator palpebrae superioris complex (d), dural sheath (e), superior ophthalmic vein (f), subarachnoid space (g), optic nerve (h), inferior rectus (i), lateral rectus (j).

septum, a fibrous structure adherent to the inner margin of the orbital rim with central portions that extend into the tarsus of the eyelids. Although there are a few orifices for passage of vessels, nerves, and ducts, the septum forms an effective barrier to prevent superficial processes from extending into the orbit proper. A pathologic process such as cellulitis may be designated *preseptal* or *postseptal*.

Technique

Computed Tomography

Intraorbital fat provides a natural source of contrast on CT scans. Most lesions within the orbit, whether inflammatory, infectious, or neoplastic, are relatively radiodense in comparison to the surrounding fat, and they are easily distinguished by CT. CT is rapid, and the images are obtained incrementally. Therefore, patient cooperation is less crucial than in MRI.

Commonly accepted protocols call for both axial and coronal images with the potential for multiplanar reconstruction. For most orbital studies, 3-mm sections in the axial and coronal planes are adequate. Coronal sections

should be initiated at the lateral orbital rim (to lessen exposure to the radiosensitive lens⁸⁰) and continued to the posterior aspect of the optic canals, with the anterior clinoid or dorsum sella used as landmarks. The axial sections should include images of the entire brain, specifically to include the retro-orbital optic apparatus, with additional retrospective magnified views of the orbits.

Coronal images are especially important in that cross-sectional evaluation of all of the intraorbital structures is optimal (e.g., extraocular muscles, optic nerve-sheath-nasal complex, vessels, and globe) (Fig. 14-1). This plane is also imperative for assessing spread of processes from surrounding structures (e.g., paranasal sinuses, trauma, tumor). The prone patient position is ideal, especially with sinus-related disease,² but supine positioning is also acceptable.

Occasionally, a patient may be unable to tolerate positioning for direct coronal imaging. This occurs most commonly with elderly patients with severe degenerative disease of the cervical spine and in the setting of acute trauma. Recent developments in multislice CT technology allow for faster thin-slice imaging. As a result, axial thin-section images can be obtained for coronal reconstruction in these patients (Fig. 14-2).

Figure 14-2. A, Coronal CT scan in a patient whose extensive dental hardware obscures detail in the orbits. B, Reformatted coronal view shows enlargement of the extraocular muscles on the left side. In view of the patient's known hyperthyroidism, this finding was thought to represent Graves' disease.

Figure 14-3. A, Axial CT scan: normal anatomy. Lens (a), lid (b), lacrimal gland (c), medial rectus (d), optic nerve-sheath complex (e), lateral rectus (f), superior orbital fissure (g). B, Axial CT scan: normal anatomy. Superior orbital vein (arrow), globe (g).

Intravenous (IV) contrast material is a necessary addition to most orbital examinations, although it is not necessary in the setting of trauma. IV contrast can increase the sensitivity and sometimes specificity of distinguishing between various entities—whether inflammatory, infectious, neoplastic, or vascular. The contrast agent can be administered by either IV drip or by mechanical injector. A single dose (e.g., 150 mL) can be used, or split doses, one for each plane or section, depending on the lesion. *Windowing* is also critical to assessing pathologic changes and should include both soft tissue and bone windows (Fig. 14-3).

Thin-section CT may be performed following the administration of contrast material into the nasolacrimal duct to evaluate patency. These CT dacryocystograms are often performed in conjunction with an ophthalmologist, who cannulates the duct and administers the contrast agent. Coronal reconstructions of the axial data can be helpful (Fig. 14-4).

Magnetic Resonance Imaging

Although MRI is relatively new, compared with CT, this modality has rapidly gained ground in the assessment of

orbital disease. The capacity to produce images without ionizing radiation and in any plane of section without a change in patient position has made MRI an important tool in orbital imaging. The absence of bony artifact is an advantage over CT, especially in the orbital apex, optic canal, and parasellar regions.

MRI uses the physical properties of the proton, the hydrogen atom's nucleus, to generate imaging data. Because hydrogen is an abundant component of the water and the macromolecules in all tissues, MRI can be used to examine any body part.

The patient is placed in a strong unidirectional magnetic field, and a small population of protons become aligned with that field. The region of interest is subjected to pulsed radiofrequency (RF) energy. This serves to change the orientation of the spinning proton. The natural tendency of the perturbed proton is to realign with the overall magnetic field. This is referred to as the *T1* characteristic of the tissue. By definition, *T1* is that time for which protons in a particular tissue have regained approximately 63% of the original alignment.

When the protons are “tipped” by the RF pulse, they

Figure 14-4. A, Coronal reformatted image from a CT dacryocystogram shows dilation of the lacrimal duct. The nasal septum and inferior turbinate are deviated leftward and cause obstruction at the valve of Hasner. B, The obstruction is only partial, as evidenced by the presence of contrast material in the posterior nasopharynx.

are initially “in phase,” or are spinning together coherently in the 90-degree frame of reference. Over time, they lose cohesion and become “out of phase,” called *T2 relaxation*.

T1 and T2 are inherent tissue characteristics and are not produced by the magnetic resonance itself. One uses the T1 and T2 of various tissues being imaged to enhance and accentuate contrast differences between those tissues.

Magnetic gradients are superimposed on the overall magnetic field to spatially “encode” the position of each spinning proton in space. One can obtain spatial information using the frequency of the spinning protons or their relative phase.

The most commonly used protocols today involve (1) *spin-echo* imaging and (2) *gradient-echo* imaging.

Spin-echo imaging involves an additional 180-degree pulse to “rephase” the protons to produce an “echo” at a specified time: TE, or *echo time*. The sequence is repeated as many times as needed to obtain information about the anatomic area of interest. TR, or *repetition time*, refers to those repeated intervals. For a more detailed review of MRI physics, see References 3, 15, 22, 45, 53, and 71.

Gradient-echo imaging involves the actual reversal of the image gradients used for spatial encoding in the region of interest. Acquisition imaging data can be obtained rapidly, either in a slice-by-slice format or volumetrically.

Shallow flip angles (<90 degrees) and faster techniques have been developed for even faster image acquisition (see specific articles on these techniques).

Gadolinium–diethylene-triamine-penta-acetic acid (Gd-DTPA) is an IV contrast agent that shortens the T1 relax-

ation time of the tissues it penetrates. This results in higher T1 signal, or “brighter” areas on the scan images. Gadolinium contrast is analogous to the iodinated contrast material used in CT scanning and identifies tissues with greater perfusion. Within the brain, gadolinium enhancement results from breakdown of the blood-brain barrier.

As in CT scans, multiple planes are important to assess the orbit. Standard protocols usually include coronal and axial T1-weighted images as well as T2-weighted axial and coronal images (Figs. 14–5 to 14–7). The imaging specialist should include the brain posterior to the orbital area in order to evaluate the cavernous sinus, optic chiasm, optic radiations, and the nuclei of the oculomotor, abducens, and trochlear nerves in the midbrain and pons.

MRI offers the ability to suppress the normally strong T1 signal of fat. Precontrast T1 imaging should be performed without fat suppression because fat suppression diminishes the inherent contrast between the high signal of fat and the lower signal of most pathologic processes. Postcontrast imaging should be performed with fat suppression techniques to increase the difference in signal between an enhancing pathologic process and its surroundings (Fig. 14–8).

Pathology

Trauma

Traumatic lesions of the orbit can involve any or all of the orbital structures. Treatment is determined by proximity to, or disruption of, key anatomic elements.

Figure 14–5. A, Coronal T1-weighted MRI study: normal anatomy. Superior orbital vein (a), lateral rectus (b), inferior rectus (c), medial rectus (d), superior oblique (e), superior rectus–levator palpebrae superioris complex (f). B, Axial T1-weighted MRI study: normal anatomy. Optic nerve in the optic canal (a), optic nerve sheath complex (b), medial rectus (c), anterior chamber (d), lens (e), lid (f), medial and lateral aspects of the orbital septum (arrows; g), lateral rectus (h). C, Axial T2-weighted MRI study: posterior visual apparatus. Position of lateral geniculate body (arrows; a), path of optic radiations (arrowheads).

Figure 14-6. Coronal T1-weighted MRI study with fat saturation: normal anatomy. A, Superior rectus/levator palpebrae superioris complex. B, Superior ophthalmic vein. C, Optic nerve. D, Lateral rectus. E, Dural sheath. F, Inferior rectus. G, Medial rectus.

One of the more common entities is disruption of an orbital wall with the potential for entrapment of extraocular muscles, the so-called “blowout” fracture. The mechanism of injury is usually blunt trauma to the anterior orbit. The increased intraorbital pressure is transmitted to the walls, resulting in fracture. The inferior and medial walls, which are thinnest, are the most vulnerable. Orbital contents are often seen to herniate through the fracture. Because of its superior bone detail, CT is the study of choice in the setting of trauma. Coronal images are essential for optimal assessment of the orbital floor. The lacrimal apparatus can also be evaluated, since it is commonly affected in trauma.⁷³

Because the extra-ocular muscles are tethered to the walls of the orbit by tiny fibrous strands that are too small to image on CT or MR, muscle entrapment can occur in the presence of an orbital blowout fracture, even without herniation of the muscle itself (Fig. 14-9).³⁴

Figure 14-7. Coronal inversion recovery, fast spin-echo MRI study: normal anatomy. A, Optic nerve. B, Subarachnoid space with cerebrospinal fluid. C, Optic nerve sheath.

Foreign body evaluation usually necessitates thin-section CT scanning (1.5 mm) to rule out clinically important objects (Fig. 14-10). Wood fragments can be particularly difficult to identify because of hydrational differences of various woods or air content. Because wood can have a variety of densities, especially on CT scans, special care should be taken to evaluate both dense foci and lucent foci within the orbit if the presence of a wood fragment is suspected.⁶²

Phthisis bulbi represents the end stage of traumatic or inflammatory injury to the globe. The result is a shrunken, atrophic, and usually heavily calcified globe.

Infection

Infection most commonly affects the orbit by extension from adjacent structures. Contiguous spread of sinusitis or a superficial periorbital cellulitis of the face is the most

Figure 14-8. A, Precontrast axial T1-weighted image performed without fat suppression demonstrates a mass at the left orbital apex in a patient with known cutaneous lymphoma. B, Postcontrast T1-weighted image of the same patient in which the fat saturation pulse failed to suppress the orbital fat (this may be due to dental artifact). The lesion demonstrates marked contrast enhancement and is now indistinguishable from the high signal of the orbital fat. This case illustrates the importance of performing nonsuppressed precontrast images and fat-suppressed postcontrast studies.

Figure 14-9. CT scan shows blowout fracture of the left orbital floor with herniation of extraconal fat and inferior rectus muscle (arrow). m, maxillary sinus.

common scenario. Hematogenous infection is less common. The specific location of an orbital cellulitis is important for prognostic and therapeutic reasons. When possible, it should be determined whether a process is (1) preseptal or postseptal or (2) intraconal or extraconal.²²

Extension of infection from the paranasal sinuses occurs most commonly from the ethmoid air cells (Fig. 14-11) in children and from the frontal sinuses (Fig. 14-12) in adults.⁶⁸ CT continues to be the examination of choice because it demonstrates not only the fluid and/or soft tissue component of the inflammatory process but also any bony changes. Findings range from mild mucoperiosteal thickening or elevation to frank intraorbital abscesses. The amount of periosteal elevation may dictate whether the patient is managed conservatively or surgically. The most common organisms in acute sinusitis are *Streptococcus pneumoniae*, beta-hemolytic streptococci, and *Haemophilus influenzae*. Staphylococci and anaerobes are less common.⁶⁸

A mucocoele is the expansion of a paranasal sinus that results from trapped mucus secretions. The expanding sinus can cause mass effect and distortion of the orbit (Fig. 14-13). MRI studies complement CT scans in this setting. In the absence of superimposed infection, the fluid is homogeneous in appearance. The fluid can have a variety of signal intensities as a result of differences in protein content from lesion to lesion. Mucocoeles are seen most often

Figure 14-10. CT scan shows intraconal, metallic, foreign bodies just medial to the medial rectus (large arrow) and intraocular (small arrow). Scleral band in place right (arrowheads).

Figure 14-11. CT scan shows an extraconal subperiosteal abscess (small arrowhead). This is a complication of ethmoid sinusitis. A thickened, displaced medial rectus (large arrowhead) and preseptal soft tissue swelling (arrows) are seen.

in the frontal sinuses but may be found in the other paranasal sinuses as well.⁶⁸

Inflammation

Graves' Ophthalmopathy

Graves' disease is one entity in the spectrum of hyperthyroidism. It is thought to be caused by a circulating stimulator of thyroid function, so-called long-acting thyroid stimulator (LATS).³² Orbital involvement demonstrates inflammatory cells that enlarge the extraocular muscles and infiltrate the retro-orbital fat. Involvement of the globe and optic nerve is rare.

The imaging findings demonstrate fusiform enlargement of the extraocular muscles, which is classically found in the belly of the muscle (Fig. 14-14; see Fig. 14-2). Typically, the tendonous attachments at the ring of Zinn are spared, which helps to differentiate Graves' disease from orbital pseudotumor. Most commonly affected is the inferior rectus muscle, both in isolation and in association with multiple muscular involvement.⁵⁴ The lack of tendonous involvement may be difficult to demonstrate in cases of massive muscle enlargement. It is important to assess for compression of the optic nerve-sheath complex, especially near the orbital apex.

In some cases, orbital involvement precedes clinically

Figure 14-12. CT scan shows subperiosteal abscess of the superior orbit (arrowheads) from ethmoid or frontal sinus disease.

Figure 14-13. Sagittal T1-weighted MRI study shows mucocoele (M) of the frontal sinus with inferior displacement of the globe (g).

apparent thyroid disease. In these circumstances, differentiation from pseudotumor can be difficult, especially when the involvement is unilateral.

Orbital Pseudotumor

Orbital pseudotumor is an idiopathic inflammatory process that may involve the extraocular muscles, orbital fat, and less commonly, other intraorbital structures.¹² The two most common appearances are a solitary intraorbital mass and diffuse muscle thickening.

The inflammation may involve any or all parts of the orbit and is usually unilateral. The diagnosis is usually based on a good clinical response to steroids⁵⁰ plus the exclusion of other inflammatory lesions of the orbit (e.g., sarcoid, Wegener's granulomatosis, multiple sclerosis). CT evaluation in the assessment of orbital pseudotumor most commonly demonstrates contrast enhancement of the involved structures, extraocular muscle enlargement, retrobulbar fat infiltration, and proptosis (Fig. 14-15A and B).

The muscular involvement in pseudotumor is classically diffuse, with extension to the tendonous attachments (Fig. 14-16). As mentioned earlier, tendonous involvement can help to differentiate pseudotumor from Graves' disease. Tumefactive or tumor-like inflammatory masses may also

occur, and differentiation from a neoplastic, infectious, or vascular process is required.

Imaging of pseudotumor and Graves' ophthalmopathy is usually accomplished with a contrast-enhanced CT scan, again with coronal and axial views essential.^{17, 46} MRI studies are also useful in evaluating involvement of the optic nerve-sheath complex.

Sarcoid

Sarcoid is a noninfectious granulomatous disease that can have manifestations in almost any part of the optic pathway, from the globe to the optic radiations. The lacrimal gland and anterior layer of the globe (Fig. 14-17) and eyelids are common areas of involvement.¹¹ This entity shows increased signal on T1-weighted images in MRI studies.⁵² Intracranial involvement by sarcoid, especially in the region of the sella turcica, is seen optimally with MRI (Fig. 14-18), although specificity and differentiation from other lesions can be difficult.

Optic Neuritis

Optic neuritis is an inflammation of the optic nerve that can have many causes, including infections (e.g., viral, bacterial, fungal, parasitic), granulomatous diseases, and demyelinating diseases such as multiple sclerosis.⁶⁸ Imaging characteristics of optic nerve inflammation are often subtle. Faint enhancement or slightly increased T2 signal may be seen. These changes are nonspecific.

Inversion recovery sequences (Fig. 14-19) are highly sensitive to increased water content, which often accompanies inflammatory processes. Increased signal on these images may be seen in optic neuritis, but this finding is also nonspecific.¹⁸

Neoplasms

Lymphoma

The most common neoplasm in the orbit is lymphoma, which accounts for just over half of all cases.⁷⁴ B-cell lymphomas of the non-Hodgkin's type are by far the most common. T-cell lineages are uncommon but have been described.⁹ Usually, orbital lymphomas are primary to the orbit, but occasionally orbital manifestation of a systemic

Figure 14-14. A, Axial contrast-enhanced CT scan shows Graves' ophthalmopathy characterized by enlarged superior, medial, and inferior recti with compromise of the orbital apex. B, Coronal contrast-enhanced CT scan of the same patient shown in A.

Figure 14-15. A, Axial CT scan shows pseudotumor of the orbit with swollen bilateral medial rectus (*arrows*), which includes tendinous insertion on the globe. Thickening and enhancement of the globe (*arrowheads*) are also shown. B, Coronal CT scan shows pseudotumor of the orbit (same patient as in A).

Figure 14-19. Coronal MRI study, inversion recovery fast spin echo, shows left optic neuritis with increased signal at the left optic nerve.

Figure 14-21. Axial T1-weighted MRI study shows optic glioma, bilateral optic nerves, with involvement of the chiasm (arrows) in a patient with neurofibromatosis.

lymphoproliferative process is seen. The usual appearance is a well-defined mass within the muscle cone (Fig. 14-20). Less frequently, extraconal masses or diffuse infiltration of the orbital fat can be seen.

The differential diagnosis includes pseudotumor and metastasis. Lacrimal gland involvement can be seen either in isolation or in combination with the other manifestations of lymphoma within the orbit.

Optic Glioma

Primary tumors of the optic nerve or nerve sheath are relatively uncommon. Optic gliomas most often occur in children, especially between the ages of 2 and 6 years, and are usually benign. This lesion usually involves the anterior optic apparatus (e.g., optic nerves, chiasm, and optic tracts) and causes enlargement and often tortuosity of these struc-

Figure 14-20. A, T1-weighted axial MRI study shows a large mass replacing the intraconal fat in the right orbit. B, T2-weighted axial image of the same patient. C, Gadolinium-enhanced axial T1-weighted image of the same patient demonstrates marked enhancement. Fat suppression allows the smaller lesion to be visible at the apex of the left orbit.

Figure 14-22. A, T1-weighted axial MRI study with gadolinium enhancement shows optic glioma of the optic chiasm (arrows). B, T1-weighted coronal MRI study with gadolinium shows same patient as in A.

tures. The incidence is increased in neurofibromatosis I (Fig. 14-21). These lesions do not calcify.¹⁰

MRI has become the modality of choice, given the necessity of evaluating the intracranial extent of the tumor (Fig. 14-22A and B). Optic gliomas are typically either nonenhancing or weakly enhancing. The lesions are generally isointense to slightly hypotense on T1-weighted images and hyperintense on T2-weighted images.²¹

CT can help in assessing bony changes and is especially valuable in detecting expansion of the optic canal. CT thus complements MRI in evaluation of these lesions.

Nerve Sheath Meningioma

The differential diagnosis of optic nerve and sheath lesions also includes meningiomas. Meningiomas tend to occur in middle-aged women rather than in children. These lesions can cause enlargement of the optic nerve sheath (Fig. 14-23A and B) or the entire complex (Fig. 14-24). Calcification is common, which helps to differentiate meningiomas from gliomas. Extension into the optic canal is rare, and extension to the chiasm is extremely rare.²⁵

MRI studies are the best modality for evaluation of these lesions, but CT can be helpful for the same reasons as with gliomas, and can also show calcifications.³⁹ Because meningiomas tend to grow outward from the nerve sheath, they are less likely to efface the CSF layer between the nerve and sheath. This property sometimes helps to distinguish meningioma from glioma.

Melanoma

Melanoma is a malignant tumor that usually originates in the uveal layers of the globe. It can extend posteriorly to the rest of the orbit. MRI studies have been used to evaluate the intraorbital extent of melanoma and to search for metastatic disease.⁵⁷

On MRI studies, the amount of melanin contained in the lesion determines the signal characteristics. Melanin shortens T1 and T2, thereby causing increased signal on T1-weighted images and decreased signal on T2-weighted images¹⁹ (Fig. 14-25).

Signal is also affected by hemorrhage, which is not uncommon in patients with melanotic lesions. With hemorrhage, the differential diagnosis includes retinal and choroid detachments from other causes (Fig. 14-26). Detachments are usually distinguished clinically and radiographically.⁴³ Gadolinium enhancement increases the sensitivity in the detection of lesions⁶ but does not increase specificity.

As previously stated, melanotic lesions have characteristic appearances, but nonpigmented melanomas cannot be reliably differentiated from other masses.⁶¹ CT can also be used to evaluate these lesions (Fig. 14-27).

Metastatic Disease

The most common tumor to metastasize to the orbit is carcinoma of breast. Other primary sites include lung, colon, and prostate (Fig. 14-28). Metastatic lesions may

Figure 14-23. A, Coronal contrast-enhanced CT scan shows optic nerve sheath meningioma (arrow). B, Axial contrast-enhanced CT scan shows same patient as in A.

Figure 14-24. Axial contrast-enhanced CT scan shows optic nerve sheath meningioma. m, meningioma; g, globe; arrow, displaced optic nerve sheath complex emerging from mass.

affect any of the intraorbital structures as well as the bony orbit itself^{30, 66} (Fig. 14-29). With a known distant primary site, a metastatic lesion should be considered. However, none of the available imaging techniques offers specificity to differentiate metastases from the many other orbital lesions. The findings may be subtle, with small areas of focal thickening of the globe, or large destructive lesions.²⁴ In addition, extension of tumor from an adjacent structure (e.g., the paranasal sinuses) may occur (Fig. 14-30A and B).

Cavernous Hemangioma and Lymphangioma

Cavernous hemangioma and lymphangioma are benign lesions that can be difficult to differentiate.⁴⁴

Cavernous Hemangioma

Cavernous hemangiomas are usually discovered in young to middle-aged adults. The lesions tend to be well encapsulated with distinct margins, are usually intraconal,⁵⁵ and grow slowly. CT demonstrates a well-margined soft tissue mass with mild or heterogeneous enhancement. MRI studies also demonstrate a well-defined intraconal lesion with isointense to slightly increased signal, when compared with the extraocular muscles on T1-weighted images. These lesions demonstrate marked signal intensity on T2-weighted images⁴⁰ (Fig. 14-31A and B).

Lymphangioma

Orbital lymphangioma presents at an earlier age, from infancy through the first decade. This lesion tends to occur either in the intraconal or extraconal compartment. Lymphangiomas are usually lobulated, with ill-defined borders, and may contain septations.²⁶ Multilocular or cystic blood collections are common.

These lesions are commonly hemorrhagic. CT scanning shows lobular heterogeneous masses with varying degrees of contrast enhancement. MRI characteristics include increased signal on T1-weighted images and marked signal intensity on T2-weighted images²⁰ (Fig. 14-32).

Retinoblastoma

Retinoblastoma is a malignant lesion with prominent tumor calcification. In its familial form, which results from loss of one copy of the Rb tumor suppressor gene,³⁵ it is

the most common intraocular neoplasm of children under 2 years of age. Inheritance is autosomal dominant. Metastasis may occur via direct spread along the optic nerve, hematogenously, or via lymphatics.

CT is the examination of choice because the hallmark finding is retinal calcification, for which MRI is less sensitive⁵⁸ (Fig. 14-33). MRI should be used as an additional modality, especially to detect extension into the region of the optic canal as well as to accomplish a more sensitive evaluation of parenchymal disease. Rarely, retinoblastoma may be seen in the pineal gland as well as in the eyes, the so-called "trilateral" retinoblastoma.

Indirect Involvement of the Orbit and Optic Pathways

The orbit or any part of the optic pathways may be affected by adjacent intracranial lesions. The most common lesions arise from the sella turcica and parasellar regions. The differential diagnosis includes pituitary macroadenoma (Fig. 14-34), meningioma, craniopharyngioma, metastasis, aneurysm, chordoma, and other less common entities. The posterior optic apparatus—superior colliculi, lateral geniculate bodies (see Fig. 14-18), optic radiation, and occipital lobes—may be affected by any infiltration or mass lesion (e.g., tumor, infarction, or inflammatory process).

Meningioma

One of the more common locations of an intracranial meningioma is the sphenoid wing. Visual symptoms can

Figure 14-31. A, Axial T1-weighted MRI study shows cavernous hemangioma of the medial right orbit. B, Axial T2-weighted MRI study shows the same patient as in A.

Figure 14-32. Lymphangioma. A, Coronal T1-weighted image. B, Coronal T2-weighted image. C, Coronal CT scan.

result from proximity to the optic canal or by mass effect on the anterior optic apparatus. Direct extension into the orbit is also possible (Fig. 14-35). On MRI studies, meningiomas are generally isointense to brain on T1-weighted and T2-weighted images with uniform, often very intense contrast enhancement.⁸³ However, signal and enhancement can be affected by the amount of calcification, vascularity, and heterogeneity of the lesion. The lesion can also show a variable amount of associated edema in the adjacent brain parenchyma.

Craniopharyngioma

Craniopharyngiomas are generally tumors of children, with a second peak in the middle-aged population. They most commonly present as a suprasellar mass. These tu-

mors are often well circumscribed and lobulated, often with cystic components. There may be a spectrum in signal characteristics on MRI scans, depending on whether the tumor is cystic or solid and whether the cysts contain high concentrations of cholesterol or hemorrhagic debris. Generally, the lesions are low to isointense on T1-weighted images and hyperintense on T2-weighted images.^{33, 59} Gadolinium enhancement of the cyst walls and solid components have been demonstrated⁷⁸ (Fig. 14-36).

Craniopharyngiomas commonly calcify. CT and MRI are complementary studies for evaluation of these lesions.

Figure 14-33. Axial contrast-enhanced CT scan shows calcified retinoblastoma of the left eye.

Figure 14-34. T1-weighted sagittal MRI study shows macroadenoma with suprasellar mass extension and superior displacement of the optic chiasm.

Figure 14-35. Axial T1-weighted MRI study with gadolinium shows left sphenoid wing meningioma (arrows), with compromise of the optic canal (curved arrow).

Lacrimal Gland and Apparatus

The most common lesions affecting the lacrimal gland are benign inflammatory processes, with tumors less common.⁴¹

Inflammatory, neoplastic, and traumatic processes can affect the lacrimal gland. The patient can present with deviation of the globe, proptosis, or conjunctival injection, depending on the extent of the lesion. With the possible exception of traumatic disruption, glandular enlargement is common to most lesions. Contrast enhancement does not distinguish between inflammation and neoplasia.

In the acute setting, viral adenitis accounts for most of the benign lesions and tends to affect a younger population. Chronic disease is usually secondary to granulomatous disease (e.g., sarcoid or Wegener's) or autoimmune disease (e.g., Sjögren's syndrome). Orbital pseudotumor may affect the lacrimal gland. Unilateral or bilateral glandular enlargement as well as variability of enhancement may be seen. The chronic entities tend to be more well margined than the acute inflammatory processes.⁴¹

Tumors of the lacrimal gland may be either benign or malignant.⁶⁵ Approximately half of the lacrimal neoplasms are tumors of epithelial origin represented by pleomorphic adenoma (also known as *benign mixed tumor*) and adenoid cystic carcinoma (Fig. 14-37). Mucoepidermoid carcinoma and adenocarcinoma are also seen. Lymphocytic hyperplasia and lymphoma (Fig. 14-38) make up the bulk of additional tumors.²⁹

CT scanning may demonstrate bone involvement in several lesions, including adenocarcinoma and mucoepidermoid carcinoma.²⁹ A study by Hesselink and coworkers²⁹ also revealed variable enhancement in both inflammatory (Fig. 14-39) and neoplastic lesions. The malignant mucoepidermoid demonstrated marked enhancement, but the adenocarcinoma showed no enhancement.

Calcified Orbital Lesions

There are many causes of orbital calcification, including such previously described entities as retinoblastoma and meningioma.⁷²

Optic Drusen

One of the more common calcified lesions is optic drusen, usually seen in adults. The cause is uncertain. Drusen occur at the junction of the nerve with the globe. Drusen are composed of complex hyaline-like collections that frequently calcify.⁷ Although these lesions may present with prominence of the optic disk, so-called pseudo-papilledema,⁶³ the actual lesion is invisible funduscopically. CT scanning is used to identify drusen^{60, 72} (Fig. 14-40).

Phthisis Bulbi

Phthisis bulbi is the degenerative end-stage of prior injury to the globe from trauma or infection. The globe is small, usually misshapen, and commonly densely calcified.

Figure 14-36. A, T1-weighted sagittal MRI study with gadolinium shows craniopharyngioma, mostly cystic, with sellar extension, and marked elevation of the chiasm, nerves, and tracts. B, Coronal T2-weighted MRI study shows the same patient as in A.

Figure 14-37. T1-weighted axial MRI study shows adenoid cystic carcinoma in the right lacrimal gland with extension to preseptal soft tissues (arrows).

Figure 14-38. A, Coronal contrast-enhanced CT scan shows left lymphoma with extension into the sinuses and anterior cranial fossa. B, Axial contrast-enhanced CT scan shows the same patient as in A.

Figure 14-39. Axial contrast-enhanced CT study shows lacrimal gland pseudotumor with extension to preseptal soft tissues on the right (arrowheads).

Figure 14-40. Axial CT scan shows optic disk drusen, right optic nerve head calcification, and optic nerve atrophy.

Figure 14-41. A, Axial CT scans shows bilateral phthisis bulbi. B, Axial T1-weighted MRI study, same patient as in A. C, Axial T2-weighted MRI study, same patient as in A.

This entity can be identified by either CT or MRI, but confirmation of calcification is made with CT (Fig. 14-41). Trochlear calcification has also been seen both with increasing patient age and with diabetes mellitus in younger patients.²⁷

Teratoma

The teratoma is a rare benign lesion that contains mixed endodermal, mesodermal, and ectodermal elements. It usually calcifies. Because the teratoma is usually seen in neonates, knowing a patient's age can help one decide whether to include this entity on a differential diagnosis^{28, 81} (Fig. 14-42).

Calcified Ciliary Muscle Insertions

Calcification of the insertions of the ciliary muscles of the pupil can be seen in elderly patients, which is often an incidental finding on CT studies of the head performed for reasons other than suspected orbital pathology.

Figure 14-42. Axial contrast-enhanced CT scan shows calcified teratoma with areas of enhancement.

Vascular Lesions

A carotid cavernous fistula is an abnormal high flow communication between the arterial and venous circulations. The most common cause is post-traumatic.⁵³ Other causes include spontaneous fistulas, possibly related to atherosclerotic disease and rupture of an aneurysm of the intracavernous portion of the carotid artery.¹⁴ Clinical findings include bruit, chemosis, exophthalmos (which can be pulsatile), visual loss, and swelling of the eyelid. Cranial nerve palsies are also seen, which may affect any of the nerves coursing through the cavernous sinus (III, IV, V1, V2, and VI).

Arteriography has been considered the "gold standard" for delineating the vascular anatomy and the site of fistulous communication.¹³ However, CT and MRI studies also have adjunctive roles in suggesting the diagnosis and also as follow-up examinations, especially after embolization.¹³ Imaging findings include proptosis, asymmetry, and distention of the affected cavernous sinus, and congestion and (usually) asymmetrical dilation of the venous structures that drain the cavernous sinus, especially the superior ophthalmic vein (Fig. 14-43A and B). Contrast enhancement, to evaluate the vascular structures, and bone windows, to evaluate fracture, are essential.³⁷

The orbital varix is a venous malformation that may be represented by a large, tortuous vein or a masslike confluence of small veins, which may markedly enlarge with changes in venous pressure (e.g., Valsalva's maneuver, straining, and exertion). The changes in venous pressure and subsequent venous distention cause a painful intermittent exophthalmos.

In the past, orbital venography was the imaging procedure of choice.³⁶ However, contrast-enhanced CT scans are currently the ideal diagnostic test. The examination is best performed with a technique for increasing orbital pressure, such as Valsalva's maneuver⁷⁷ (Fig. 14-44A and B) or even with a gentle venous compression on the neck.⁶⁴ In addition, color flow Doppler imaging may be useful as a screening examination for a varix.⁷⁶

Figure 14-43. Carotid cavernous fistula. *A*, Coronal T1-weighted MRI study shows marked enlargement of the left superior ophthalmic vein (arrow). *B*, Lateral digital subtraction angiogram shows fistulous communication between branches of the external carotid and the cavernous sinus. m, middle meningeal artery; F, fistula; c, cavernous sinus.

Figure 14-46. Septo-optic dysplasia MRI. A and B, Absent septum pellucidum, absent chiasm (coronal and sagittal MRI, T1-weighted). C, Atretic optic nerves (coronal CT scan).

Congenital Abnormalities and Anomalies

Coloboma

Optic nerve colobomas are congenital defects in the optic nerve usually near the optic disc. These lesions represent a spectrum of developmental abnormalities that result from incomplete or inadequate fusion of the optic fissure during embryogenesis and occur along the inferomedial aspect of the globe and nerve.⁴⁵ The defects can be bilateral and can be transmitted as an autosomal dominant trait.⁶⁴ They may present as a small cone-shaped defect at the optic disc or as a large retinal cyst. CT scans have been used to delineate the various elements of this lesion,⁶⁶ and thin-section axial scans through the region of the optic disc, in particular, are suggested⁴² (Fig. 14-45).

Septo-optic Dysplasia

Septo-optic dysplasia is the mildest form of a spectrum of developmental abnormalities that includes holoprosencephaly. These abnormalities result from abnormal ventral induction and mesodermal differentiation. In septo-optic dysplasia, absence of the septum pellucidum and hypoplasia of the optic nerves is sometimes accompanied by pituitary or hypothalamic endocrine dysfunction.⁴⁹

These abnormalities are often accompanied by or associated with other congenital and migrational defects.⁸ MRI is therefore the modality of choice in evaluating these lesions,⁵ especially because of the multiplanar capabilities and superior visualization of the sellar region, optic nerves

and chiasm, and the septum pellucidum. Coronal views are especially important for evaluating the septum⁷⁸ (Fig. 14-46). Optic nerve hypoplasia may be present *without* an absent septum.

Summary

Imaging of the orbit by CT and MRI has undergone many recent technologic advances. With attention to technique, the localization and characterization of lesions can be made without difficulty. However, specificity is still an issue with many of the described lesions, and clinical correlation is essential for diagnosis.

Temporal Bone

Donald W. Chakeres, Mark A. Augustyn

Many imaging modalities are available for the evaluation of the temporal bone, including plain radiographs, angiography, cerebrospinal fluid (CSF) analysis, air and non-ionic contrast cisternography, computed tomography (CT), and magnetic resonance imaging (MRI). CT and MRI are currently the most widely used techniques and have largely replaced the other modalities.^{2, 3, 5, 8-10, 12, 14, 31, 57, 67} Plain films remain an inexpensive survey of large bony and air-filled structures although they often result in inaccurate diagnosis.

CT scanning excels in the evaluation of bone and air space anatomy and disorders. Because CT scans are more accurate in identifying many soft tissue abnormalities and are much less prone to artifacts,¹⁶ they have largely replaced polytomography; there is also less radiation to the lens of the globe with CT scans than with polytomography.¹⁴ With advances in MR technology, MRI has surpassed CT in certain areas of spatial and contrast resolution.⁷

MRI has expanded the range of pathology that can be accurately evaluated because it can image many soft tissue entities not visible by other techniques. MRI studies can also be extremely useful in the evaluation of blood vessel-related disorders of the temporal bone and is much better than CT in characterizing the CSF, brain, and cranial nerves.

Angiography is still the "gold standard" for vascular evaluation, and interventional angiography can be used in treatment of vascular lesions of the temporal bone. Each technique has its own advantages and disadvantages, and often more than one examination is necessary for a complete temporal bone evaluation.³⁹

Normal Temporal Bone

Embryology and Development

The development of the *inner ear* structures (vestibule, semicircular canals, internal auditory canal [IAC], cochlea) is independent of the *middle ear* (ossicles, mastoid antrum, tympanic membrane, middle ear air spaces) and *external ear* (external auditory canal [EAC], temporomandibular joint) structures. This explains why developmental abnormalities of the inner ear are usually not seen with deformities of the external ear and middle ear, and vice versa.²³ The mechanical sound-conducting structures of the external ear and middle ear develop from the first and second branchial arches. The neural sound-perceiving apparatus of the inner ear develops from the ectodermal otocyst. Adjacent mesenchyme contributes to the development of the inner ear, middle ear, and external ear.

The first and second branchial arches mold two signifi-

cant cartilaginous structures. The first arch forms Meckel's cartilage, from which the head of the malleus and short process of the incus develop. The second arch forms Reichert's cartilage, from which the remainder of the malleus and incus, styloid process, and stapes superstructure develop.⁵⁵ The stapes footplate is a bilaminar structure, with an outer portion developing from Reichert's cartilage and an inner portion developing from the ectodermal otocyst.

The middle ear cavity and mastoid antrum are fluid-filled until birth. The neonate's initial crying and breathing fill the eustachian tube system and the middle ear with air. The mastoid air cells develop as saclike extensions from the mastoid antrum, commencing at about the time of birth and continuing for several years. There is extensive variation in the degree of pneumatization. Incomplete pneumatization of the mastoid air cells may be caused by a lack of proper function of the eustachian tube during early life.⁴⁷

Normal Anatomy (Figs. 15-1 to 15-15)

External Auditory Canal

The external auditory canal consists of a funnel-shaped, undulating, cartilaginous lateral portion and an osseous medial segment (see Figs. 15-3, 15-9, and 15-10).¹¹ The cartilaginous portion is continuous with the pinna. These structures are flexible and are surrounded by fat. The osseous portion constitutes two thirds of the length of the external auditory canal and is covered by skin and periotum only.

Tympanic Cavity

The tympanic cavity is the air space between the eustachian canal and the mastoid air cells (see Figs. 15-7 and 15-8) that contains the ossicles. The *hypotympanum* is the most inferior portion of the tympanic cavity and connects anteromedially to the osseous orifice of the eustachian canal. The semicanal for the tensor tympani muscle parallels the eustachian canal. The protympanum forms the anterior triangular portion of the tympanic cavity adjacent to the carotid canal.

The *mesotympanum*, the central portion of the tympanic cavity, is bordered laterally by the scutum (or spur) and tympanic membrane and medially by the otic capsule. The scutum is a bony crest separating the external auditory canal from the epitympanic space. The tympanic membrane attaches to the scutum superiorly and to the limbus inferiorly.²²

The *post-tympanum*, the posterior portion of the cavity, contains the facial recess laterally and the sinus tympani

Figure 15-1. Temporal bone, diagram of normal anatomy.

A, Diagram simulating a lateral CT scout view of the skull. The 0-degree plane represents the anthropologic baseline (through the external auditory canal and inferior orbital rim). The recommended CT planes (30 and 105 degrees) are illustrated. The internal temporal bone structures are consistently oriented to these external landmarks.

B, Schematic of the lateral view of the temporal bone that depicts the normal relationship of several major temporal bone structures.

C, Spatial relationship of the normal temporal bone structures to the anthropologic baseline. The four recommended tomographic planes (0, 30, 70, and 105 degrees) correspond to the scan planes through the temporal bone based on the scout positioning.

(A-C, From Chakeres DW, Spiegel RK: A systematic technique for comprehensive evaluation of the temporal bone by computed tomography. *Radiology* 146:97, 1983.)

medially. The triangular epitympanum forms the superior portion of the middle ear and contains the massive portions of the malleus (head) and the incus (body and short process). The epitympanic space is linked to the mastoid antrum by a narrow hourglass-shaped isthmus called the aditus ad antrum.

Mastoid Antrum

The cone-shaped antrum is interposed between the aditus ad antrum and the mastoid air cells (see Fig. 15-6). The size of the antrum varies considerably as a result of the alterations in pneumatization of the air cells that drain into it.

Ossicles

The ossicles are suspended by the tympanic membrane, the ligaments to the epitympanic walls, and the oval window (see Figs. 15-5, 15-7, and 15-13). The long process of the malleus attaches to the tympanic membrane. The neck of the malleus is connected to the tensor tympani

ligament. The circular head of the malleus articulates with the triangular body of the incus. The short process of the incus is suspended within the epitympanic space, pointing toward the aditus ad antrum. The long process of the incus articulates with the stapes.

The stapes consists of two crura and one footplate. The footplate of the stapes attaches to the oval window of the vestibule and is secured by the annular ligament.²⁴

Internal Auditory Canal

The internal auditory canal is a bony conduit that transmits cranial nerves VII (facial) and VIII (vestibulocochlear) from the pontomedullary junction of the brain stem to the inner ear (see Figs. 15-5 and 15-8). Its medial orifice is the porus acusticus. The internal auditory canal is partially divided by a central anterior bony lamina called the *falciform crest* (Fig. 15-15A), which runs parallel to the long axis of the canal. The falciform crest divides the canal into a smaller superior portion containing the superior vestibular and facial nerves and a larger inferior portion containing

Figure 15-2. Hypotympanic jugular foramen level.

A, Axial CT section acquired through the right temporal bone.

B, High-resolution time-of-flight MRI study at a similar level where the vessels demonstrate a high signal intensity. cc, vertical carotid canal; dfn, descending facial nerve; eac, external auditory canal; ht, hypotympanum; jb, jugular bulb; mc, mandibular condyle; pf, petro-occipital fissure; ss, sigmoid sinus; tmj, temporomandibular joint.

C, Surface CT reconstruction, inferior view of temporal bone. This surface reconstruction of the inferior skull base has been processed from axial CT images. The openings for the carotid canal, jugular fossa, foramen ovale, foramen spinosum, and the stylomastoid foramen are all visible. The mandible, mastoid tip, cut end of the styloid process, external auditory canal, petrous apex, clivus, petro-occipital fissure, and stylomastoid foramen are shown.

Figure 15-3. Axial views, normal anatomy.

A, Axial CT section. This is the most inferior CT axial section of the temporal bone. The external auditory canal and the long process of the malleus are seen. The tympanic membrane is too thin to be visible. The cochlear promontory and basal turn of the cochlea are visible. The thin, linear semicanal of the tensor tympani muscle is seen interposed between the protympanum and the carotid canal. The cochlear duct is seen arching from the posterior fossa toward the basal turn of the cochlea. The descending facial nerve canal, sigmoid sinus, and the mastoid air cells are shown.

B, Axial MRI section.

Figure 15-4. Axial views, normal anatomy.

A, Axial CT scan of the left temporal bone centered at the neck of the malleus in the epitympanic space. The adjacent long process of the malleus and the stapes are both visible posteriorly. The semicanal of the tensor tympani muscle is seen as a linear lucency just lateral to the cochlea. The ligaments are not visible. The three turns of the cochlea are all visible as well as the air space related to the round window niche. The descending facial nerve canal is seen posterior to the tympanic sinus and anterior to the mastoid air cells. Other labeled structures include the petrous apex, carotid canal, and the sigmoid sinus.

B, Axial MR image.

Figure 15-5. Axial views, normal anatomy.

A, Axial CT image centered over a long segment of the facial nerve canal. The geniculate ganglion and horizontal portions of the facial nerve canal are seen continuous with the internal auditory canal. The superior portion of the cochlea and the vestibule are visible. The opening of the vestibular aqueduct and endolymphatic sac is seen as a thin slit along the posterior margin of the temporal bone just medial to the mastoid air cells. The epitympanic space holds the head of the malleus and the body of the incus and is continuous posteriorly with the aditus ad antrum and the mastoid antrum.

B, Axial MR image.

Figure 15-6. Axial views, normal anatomy.

A, Axial CT section of the complete internal auditory canal, ending in the proximal limb of the geniculate segment of the facial nerve canal anteriorly. The vestibule and complete lateral semicircular canal are visible. The posterior semicircular canal and the vestibular aqueduct are seen posteriorly. Portions of the epitympanic space, the aditus ad antrum, and the mastoid antrum are seen in continuity. Koerner's septum is also visible. The squamous portion of the temporal bone is seen anterior to the mastoid and petrous segments.

B, Axial MR section.

C, Axial 3D reconstruction of the interior of the skull base clipped at the level of the internal auditory canal. The relationship of the temporal inner and the middle ear structures to the skull base is shown.

Figure 15-7. Normal anatomy.

A, Coronal CT section. This is the most anterior CT section of the left temporal bone. The scutum forming the medial margin of the external auditory canal and adjacent head of the malleus and the long process of the malleus are seen. The epitympanic space supports the ossicles. The external auditory canal appears continuous with the middle ear cavity; the tympanic membrane is frequently not visible when normal. Abnormal thick tympanic membranes are easier to image. Three small canals are just medial and superior to the anterior cochlea. These include the proximal limb of the geniculate ganglion, the distal limb of the geniculate ganglion, and the semicanal of the tensor tympani muscle.

B, Axial MR section.

Figure 15-8. Normal anatomy.

A, Coronal CT section made at the level of the oval window. The adjacent stapes and incudostapedial joint are visible as an L-shaped structure overlying the oval window. The horizontal portion of the facial nerve is just below the lateral semicircular canal. The short process of the incus is interposed between the scutum and the lateral semicircular canal. The internal auditory canal (IAC), middle ear, external auditory canal (EAC), stapes, and the basal turn of the cochlea are shown. Note the absence of visible soft tissues over the medial EAC, which is normal. Only the cartilaginous segment of the EAC is seen as a soft tissue component.

B, Coronal MR section.

C, Surface MRI reconstruction. This is an oblique view of the left otic capsule structures imaged by high-resolution 3D Fourier transform MRI T2-weighting and postprocessing with a surface algorithm. The three turns of the cochlea are clearly seen, with the basal turn merging with the vestibule. The superior, lateral, and posterior semicircular canals are all well visualized. The cerebrospinal fluid (CSF) in the internal auditory canal is seen as a tubular structure extending back toward the cerebellopontine angle. The anatomy appears as a "plaster cast" of the otic capsule.

Figure 15-9. Coronal views, normal anatomy. A, Coronal CT section of the left temporal bone, made through the vestibule and the posterior portion of the oval window. The basal turn of the cochlea and cochlear promontory are seen. The aditus ad antrum is seen just lateral to the lateral semicircular canal. A short portion of the superior semicircular canal is visible. The internal auditory canal, middle ear, styloid process, and external auditory canal are shown. B, Coronal MR section.

Figure 15-10. Coronal views, normal anatomy. *A*, Posterior coronal CT section of the temporal bone centered at the level of the round window and the tympanic sinus. The air spaces extend all the way to the otic capsule membrane surfaces. The adjacent posterior genu of the facial nerve and vestibule are seen. Other depicted structures include the posterior internal auditory canal, superior semicircular canal, lateral semicircular canal, styloid process, and external auditory canal. *B*, Coronal MR section.

Figure 15-11. Coronal CT section. This is the most posterior section of the temporal bone. The descending facial nerve canal is seen between the mastoid air cells and the more medial jugular fossa. The jugular tubercle, hypoglossal canal, and occipital condyle all appear medial to the jugular fossa. Short segments of the posterior semicircular canal are seen.

the inferior vestibular and cochlear nerves.²³ The lateral portion of the canal is perforated by the cranial nerves where they enter the cochlea, vestibule, and facial nerve canal.

Vestibule, Vestibular Aqueduct, Endolymphatic Duct, and Sac

The vestibular cavity is the central portion of the membranous labyrinth that communicates with the semicircular canals and cochlea (see Figs. 15-6, 15-10, and 15-14). The vestibule lies immediately lateral to the fundus of the internal auditory canal, and the oval window of the middle ear forms its lateral margin. The vestibular aqueduct is a narrow bony canal that contains the small endolymphatic duct and sac (see Fig. 15-14). The endolymphatic duct originates from the posteromedial aspect of the vestibule, courses past the common crus,⁵ and assumes a hockey stick shape. The endolymphatic sac, an extension of the endolymphatic duct, is a dead-end fluid space arising from the vestibule that lies beneath the dura of the posterior temporal bone.

Semicircular Canals

The semicircular canals are three orthogonally arranged circular structures of the membranous labyrinth arising from the vestibule (Figs. 15-6, 15-8, and 15-13). The lateral semicircular canal approximates the horizontal plane. The posterior and superior semicircular canals share a common crus posteriorly.

Cochlea and Cochlear Aqueduct

The spiral cochlear apparatus contains the membranous labyrinth components for hearing (see Fig. 15-4). The cochlea lies anterior to the vestibule and has $2\frac{1}{2}$ to $2\frac{3}{4}$ turns around its modiolus, the central bony spiral axis. The most lateral portion of the basal turn of the cochlea projects into the tympanic cavity, forming a promontory of bone.³⁰

The cochlear aqueduct, a channel that connects the cochlea near the round window with the subarachnoid space just superior to the jugular tubercle, lies inferior to the internal auditory canal.

Oval and Round Windows

The oval window of the vestibule is the interface between the mechanical and neural elements of the ear (see Fig. 15-8). It lies just inferior to the horizontal facial nerve canal and the lateral semicircular canal. It is covered by the annular ligament, which surrounds the footplate of the stapes.²³

The round window is the bony opening of the basal turn of the cochlea and is covered by a fibrous membrane (see Fig. 15-10). It lies inferior and slightly posterior to the oval window and is adjacent to the inferior tympanic sinus.

Facial Nerve and Facial Nerve Canal (Fallopian Canal)

The facial nerve has a highly tortuous course and comes in close contact with almost every other important component of the temporal bone (Figs. 15-5, 15-8, and 15-12). The labyrinthine (cochlear) portion of the facial nerve

Text continued on page 511

Figure 15–12. Sagittal views, normal anatomy. *A*, Sagittal CT reconstruction through the descending facial nerve canal and stylomastoid foramen. The mastoid air cells and sigmoid sinus lie just posterior to the facial nerve. The mandibular condyle, mandibular fossa, external auditory canal, and epitympanic space are visible. *B*, Sagittal MRI section. *C*, CT surface reconstruction of the lateral skull and mandible centered over the external auditory canal.

Figure 15-13. Sagittal views, normal anatomy. *A*, Sagittal CT reconstruction made at the level of the epitympanic space. The most medial portion of the mandibular condyle and the mandibular fossa are seen. The styloid process and the mastoid air cells are visible. The head of the malleus and the long process of the incus are visible in the epitympanic space. The thin wall of the epitympanic space, the semicircular canals, and a portion of the facial nerve canal in the middle ear are visible. *B*, Sagittal MR section.

Figure 15-14. Sagittal views, normal anatomy. *A*, Sagittal CT reconstruction centered at the level of the middle ear. The oval and round windows are seen with their associated niches. The vestibule and the basal turn of the cochlea are seen as well. The superior and posterior semicircular canals are visible. The tympanic sinus is continuous with the round window. *B*, Sagittal MR section.

Figure 15-15. Sagittal views, normal anatomy. *A*, This sagittal CT reconstruction is the most medial section and is centered at the protympanum, carotid canal, internal auditory canal, and jugular fossa. Note the close association of the protympanum and the carotid canal. The internal auditory canal demonstrates a small anterior pointed indentation resulting from the falciform crest that separates the facial and cochlear nerves. *B* and *C*, Sagittal MR sections.

Figure 15-15 Continued

exits the superior anterior portion of the internal auditory canal fundus.

At the geniculate ganglion, an acute reverse (inverted V) angle of the nerve and canal is seen. The distal limb of the geniculate ganglion doubles back posteriorly to become the horizontal segment in the medial wall of the tympanic cavity. This portion of the facial nerve canal has a thin inferior bony covering that may be dehiscence.

The horizontal portion of the facial nerve runs directly inferior to the lateral semicircular canal. The facial nerve then abruptly turns inferiorly (at an angle of 95 to 125 degrees) to form the posterior genu near the tympanic sinus and the pyramidal eminence.⁵³

The vertical, or descending, facial nerve in the mastoid portion of the facial nerve canal runs vertically just posterior to the external auditory canal. In this vertical portion, the nerve to the stapedius muscle and the chorda tympani (first and second branches, respectively, of the facial nerve distal to the geniculate ganglion) arise. The facial nerve then exits from the mastoid portion of the temporal bone via the funnel-shaped, fat-filled stylomastoid foramen.

Carotid Canal

The carotid canal enters the base of the skull, ascends vertically, then turns horizontally and medially toward the petrous apex (see Figs. 15-2 and 15-15). This canal lies anterior and inferior to the cochlea and is separated from the protympanum by a thin bony plate.

Jugular Foramen and Fossa

The jugular foramen is divided into a smaller anteromedial neural compartment (pars nervosa) containing cranial nerves IX, X, and XI, and a larger posterolateral vascular compartment (the pars vascularis) containing the jugular vein (see Fig. 15-11). The floor of the tympanic cavity normally forms the roof of the jugular fossa. The jugular bulbs are frequently asymmetrical, and there may be a small diverticulum from their apices.

CT and MRI Anatomy

CT scans and MRI studies are complementary. On CT scans, bony structures are demonstrated by high density

and CSF by low density, and air spaces appear black. The brain and vascular structures are intermediate in density. CT is not ideal for evaluating detail of the soft tissues of the otic capsule contents, brain, and vessels. In contrast, MRI studies receive no signal from dense bone or air spaces and thus cannot be used to evaluate these components accurately in the absence of pathology. MRI, however, is superior to CT in characterizing the CSF, brain, cranial nerves, and blood vessels.

CT Techniques

The temporal bone has a high inherent radiation attenuation contrast, having both the most dense bone in the body as well as air-filled spaces. High-resolution CT images are usually acquired with thin sections (1 to 2 mm) and special bone algorithms for high detail.¹⁴ CT scans of the temporal area can be obtained rapidly, with relatively low radiation doses, compared with many other types of CT examinations. Contrast enhancement is not essential for evaluation of pathology isolated to bone or air spaces. Intravenous (IV) contrast material is often used to assess vascular lesions, areas of breakdown in the blood-brain barrier, or soft tissue changes. CT is less expensive than MRI, although CT is limited by scan artifacts, radiation exposure, and fewer scanning planes (because of the limitations in gantry and in patient positioning).

Multiplanar CT reformations can display the complex anatomy of the temporal bone in all of the conventional polytomography projections while exposing the patient to radiation only once.²⁵ However, even slight motion by the patient is intolerable because the small bony structures of the temporal bone are in such close proximity that motion artifacts may obscure significant detail.⁶³ In addition, reformation results in slight image degradation and loss of resolution. The longitudinal oblique plane (Stenvers projection) is parallel to the long axis of the petrous bone and is ideal for the study of longitudinal temporal bone fractures.⁶⁰

MRI Techniques

Many different techniques can be used to acquire MR images, depending on the suspected abnormality and the equipment available. T1-weighted (TR = 600 msec, TE = 20 msec) spin-echo coronal or axial images are usually acquired without contrast medium. The fat spaces have high signal intensity, and the brain has intermediate signal intensity. CSF demonstrates low signal intensity, and air and bone spaces appear as voids. This sequence also helps to differentiate fat from subacute hemorrhage.

T2-weighted (TR = 3000 or longer msec, TE = 80 or longer msec) axial spin-echo images accurately display the CSF spaces and many disease processes as high-signal-intensity regions. High-resolution, thin-section (1.5 mm or less), three-dimensional (3D) Fourier transform (3D FT) T1-weighted, gradient-echo (TR = 50 msec, TE = 7 msec; flip-angle, 30 degrees) images can be acquired with paramagnetic contrast agents. Gradient images have the advantage of high resolution, very thin sections, and blood flow information (phase or time-of-flight effects).^{15, 59}

Various image contrasts are also possible, including T1, free precession, or proton-density weighting. T2-weighted,

spin-echo 3D FT imaging using multiple echo times (TE) in for each repetition time (TR) generate excellent quality images. T2-weighted or free precession at steady-state gradient-echo 3D FT imaging (SIMCAST*) with very high resolution displays the otic capsule structures as high-signal-intensity regions surrounded by signal void.⁷ Three-dimensional data can also be computer-processed into maximum pixel signal intensity ray projections, planar sections, or surface reconstructions.⁵⁷

MRI is outstanding for its ability to evaluate blood vessel-related disorders of the temporal bone.^{48, 59} With many gradient-echo techniques, flowing blood can be seen as a high-intensity-signal region,¹⁵ and phase imaging can be used to quantify velocity and flow volumes.⁵⁹ Gadolinium-diethylenetriamine-penta-acetic acid (Gd-DTPA) contrast-enhanced MRI studies using T1-weighted images are particularly sensitive for evaluating abnormalities that alter the blood-brain barrier or that are vascular, such as inflammatory disease (Bell's palsy, vestibulitis, otitis, granulation tissue, meningitis), carcinomatosis, posterior fossa infarcts, tumors,^{6, 38} and demyelination.⁵⁰ Frequently, the findings of contrast enhancement are more obvious on MR images than on CT scans. MRI studies, compared with CT, also have higher resolution and are more sensitive to alteration in the fluid spaces of the inner ear and the cerebellopontine angle.

Normal Temporal Bone Images

Axial Sections

Caudad to Cephalad (see Figs. 15-1 to 15-6)

The axial or transverse plane is most suitable for a survey study of the temporal bone.⁶⁸ This suitability is based on the ease by which axial CT sections may be obtained.⁶³ The structures within the temporal bone are consistently oriented to the external landmarks of the skull. Axial CT sections made 30 degrees above the anthropologic baseline are parallel to the lateral semicircular canal and optimally display many structures.¹⁴ The axial plane is of special interest for the visualization of the incudomalleolar and incudostapedial articulations, facial nerve canal, internal auditory canal, vestibular aqueduct, lateral semicircular canal, and the oval and round windows.

Axial Hypotympanic-Jugular Foramen Level
(see Fig. 15-2)

The carotid canal lies just anterior to the jugular fossa, forming a "snowman"-like configuration. The carotid canal is usually smaller than the jugular fossa, and both demonstrate sharp cortical margins. Inferiorly, only a small spine separates the two as they converge to enter the carotid sheath. The hypotympanum is adjacent to these structures. The opening of the eustachian canal is triangular, with the apex extending parallel to the carotid canal.⁹ The petro-occipital fissure separates the temporal bone from the occiput.

The mandibular condyle and temporomandibular joint

*SIMCAST, segmented interleaved motion compensated acquisition in the steady-state technique.

can also be seen on CT scans. On MRI gradient-echo studies, the descending portion of the facial nerve can be seen just lateral to the jugular bulb, and the blood vessels can be seen as high-signal-intensity regions because of flow effects.

Axial Inferior Tympanic Level (see Fig. 15-3)

On CT scans, the anterior and posterior walls of the bony external auditory canal demonstrate dense sharp cortical margins without soft tissue covering. The anterior margin of the external auditory canal forms the posterior lip of the temporomandibular joint. The cartilaginous segment is surrounded by fat that is of low density on CT scans and of high signal intensity on T1-weighted MRI studies.

The descending facial nerve canal is easily identified on CT scans as a well-marginated circular lucency in the temporal bone posterior to the external auditory canal. On MRI studies, the facial nerve is seen as an intermediate-signal-intensity to high-signal-intensity circular structure, surrounded by a large area of signal void of the temporal bone and mastoid air spaces.

The carotid canal can be seen early in its anteromedial course through the skull base, parallel and medial to the semicanal of the tensor tympani muscle at this level. On CT scans, the medial funnel-shaped opening of the cochlear aqueduct can be seen as a triangular lucency facing the cerebellopontine angle. Its apex points toward the round window. The opening of the duct may be large and mimic the internal auditory canal. The long process of the malleus parallels the tympanic membrane.

Axial Midtympanic Level (see Fig. 15-4)

The middle ear cavity is highly complex but is constant in size and configuration among patients. The normally thin tympanic membrane is often invisible on axial CT sections. The long process of the malleus lies parallel and anterior to the long process of the incus.

The axial projection is ideally suited for demonstrating the cochlear aqueduct as a thin canal within the dense cortical bone, progressively enlarging from lateral to medial. The duct is demonstrated on CT scans but not well seen on MRI studies, possibly because of the combination of its small diameter and CSF motion artifacts.

The complex medial margin of the middle ear includes the cochlear promontory, oval and round windows, cochleariform process, tensor tympani tendon, pyramidal eminence, stapedial tendon, and lateral semicircular canal. Unless there is fluid or a mass within the middle ear, MRI cannot be used to depict these structures. On CT scans, the apical, second, and basal cochlear turns are seen at this level. On MRI studies, these fluid-filled structures are identified by their intermediate signal intensity.

Axial Epitympanic Internal Auditory Canal Level (see Fig. 15-5)

CT images at this level display the round head of the malleus and triangular body of the incus in the characteristic "ice cream cone" configuration (incudomalleolar articulation). The stapedial superstructure is occasionally seen,

forming an arch over the oval window on high-resolution CT scans. The internal auditory canal is slightly funnel-shaped and ends in an ovoid vestibule.

These canals should be nearly symmetrical. Although there is wide variation in the exact shape and size of the canals, asymmetry of greater than 2 mm suggests pathology. Lower-resolution MRI studies can demonstrate CSF in the canal, and high-resolution MRI studies can actually demonstrate the individual nerves as filling defects within the CSF.

On CT scans, the descending facial nerve canal is seen just lateral to the sinus tympanum. On MRI studies, the cochlear fluid contents, labyrinthine and horizontal segments of the facial nerve, and the geniculate ganglion are all seen as intermediate-signal-intensity structures surrounded by the signal void resulting from their bony walls.

Axial Lateral Semicircular Canal Level (see Fig. 15-6)

The axial projection is excellent for visualizing the entire lateral semicircular canal, since both are 30 degrees above the anthropologic baseline. The vestibular aqueduct is seen as a thin, hockey stick-shaped bony lucency. On MRI studies, the endolymphatic duct and sac appear as thin, high-signal-intensity regions. The endolymphatic duct extends posteriorly from the region of the common crus. It then abruptly turns laterally between the posterior margin of the temporal bone and the posterior semicircular canal.⁹

The mastoid antrum lies posterior and lateral to the aditus ad antrum and opens into many mastoid air cells. It is bordered superiorly by the tegmen tympani, which may be extremely thin and not well visualized on CT scans. The medial margin of the antrum is the promontory formed by the otic capsule of the lateral semicircular canal. On CT scans, the posterior semicircular canal and its ampulla are demonstrated.

Coronal Sections

Anterior to Posterior (see Figs. 15-1 and 15-7 to 15-11)

Coronal CT sections are particularly useful in the evaluation of the ossicles, geniculate ganglion, oval window, stapes, jugular fossa, middle ear walls, and roof (tegmen tympani) of the tympanic cavity.⁴ The internal auditory canal and vestibule as well as Koerner's septum, which separates the squamous and petrous portions of the temporal bone, may also be identified.

Coronal Anterior Tympanic Level (see Fig. 15-7)

This plane offers excellent visualization of the superior and inferior walls of the external auditory canals. The tympanic membrane often is not visible, but it may be identified as a thin, filamentous structure extending from the scutum superiorly and coursing parallel to the plane of the long process of the malleus to attach to the limbus inferiorly.¹¹ The head of the malleus can be seen in the epitympanic space, and the floor and roof (tegmen) of the middle ear are also well visualized on CT scans.

The basal and second turn of the cochlea, geniculate ganglion, and internal auditory canal are identified on CT scans, surrounded by the dense bone of the otic capsule.

The cochlea and geniculate ganglion can be directly viewed on MRI studies by their fluid and soft tissue signal intensity.

Coronal Midtympanic Level (see Fig. 15–8)

The CT image at this level shows the body of the incus and incudostapedial articulation as an L-shaped configuration. The stapes projects medially and superiorly from the body of the incus toward the oval window (above the cochlear promontory). The proximal limb of the geniculate ganglion is seen just superior and lateral to the cochlea.

Beneath the lateral semicircular canal, the horizontal portion of the facial nerve canal appears as a small circular structure.⁵³ The floor and roof (tegmen) of the middle ear are well visualized on CT scans. On MRI studies, the facial (VII) and vestibulocochlear (VIII) nerves can be seen together in the internal auditory canal, diverging laterally.

Coronal Oval Window Level (see Fig. 15–9)

The full extent of the internal auditory canal, which often includes the central crista falciformis dividing the canal into two portions, is well visualized at this level. On CT scans, the oval window is seen as a bony defect of the lateral portion of the vestibule. The stapes is oriented slightly superiorly toward the oval window, just inferior to the lateral semicircular canal and the horizontal facial nerve.

Coronal Posterior Middle Ear Level (see Fig. 15–10)

The posterior middle ear has several small niches. One of the niches is the tympanic sinus, which extends between the vestibule and the pyramidal eminence. The second niche extends toward the round window. The epitympanic space lies just lateral to the lateral semicircular canal.

Coronal Jugular Foramen Level (see Fig. 15–11)

The jugular foramen and bulb frequently have a dome-shaped outline. The descending portion of the facial nerve canal may be identified running nearly vertical, directly inferior to the lateral semicircular canal. The mastoid antrum is seen superiorly and laterally. On CT scans, this section reveals various segments of the semicircular canals as well as the articulation of the occipital bone and atlas. Just lateral to this, the descending facial nerve is seen over a long section coursing toward the stylomastoid foramen.

Sagittal Images (see Figs. 15–12 to 15–15)

Direct sagittal images or reformations²⁵ can show the relationship of the mandibular condyle to the glenoid fossa and external auditory canal. The external auditory canal may be seen lateral to the tympanic membrane or long process of the malleus. The aditus ad antrum, mastoid antrum, and tegmen tympani are all well demonstrated.

The third portion of the facial nerve canal, the internal and external auditory canals, and the vestibular aqueduct are also well visualized on sagittal images.¹¹ MRI studies can demonstrate the individual nerves in the internal auditory canal, with the facial nerve superior and anterior, the cochlear nerve inferior and anterior, and the vestibular nerves posterior.

Sagittal Descending Facial Nerve Level (see Fig. 15–12)

The circular external auditory canal lies just below the ossicles in the epitympanic space. On CT and MRI scans, the descending facial nerve and posterior genu form an upside-down hockey stick shape. On MRI studies, the soft tissue components are easily seen.

Sagittal Vestibular Level (see Fig. 15–13)

Sagittal sections through the lateral vestibule demonstrate the multiple small components of the individual semicircular canals.

Sagittal Common Crus Level (see Fig. 15–14)

The vestibule, cochlea, and semicircular canals form an “x”-like configuration on sagittal sections. The vestibule is central, and the common crus of the superior and inferior semicircular canals can be seen just posterior and superior to the vestibule on both CT scans and MRI studies. The vestibular aqueduct appears as a thin, linear structure underlying a flange of the posterior petrous bone on CT scans, and the contained endolymphatic duct and sac can be seen on MR images. On MRI studies, the endolymphatic sac can be seen as a triangular area of increased signal at the distal end of the endolymphatic duct.

Sagittal Internal Auditory Canal Level (see Fig. 15–15)

On sagittal sections, the petrous apex has a triangular configuration. On CT scans, the circular internal auditory canal may demonstrate a small ridge anteriorly, related to the falciform crest. On high-resolution MRI studies, the individual nerves can be seen as filling defects. The carotid canal and the jugular fossa are directly inferior to the other otic capsule structures.

Abnormal Temporal Bone Congenital Malformations

Evaluation of the congenitally deaf child is very difficult. Audiologic testing, although frequently not specific, is imperative to distinguish neurosensory defects from conductive hearing problems. Neurosensory defects occur medial to the oval window and are caused by maldevelopment of the otocyst. Conductive defects occur in the external and middle ears as a result of anomalies of the branchial arch derivatives.

CT scanning is essential in evaluation of the patient with known or suspected structural deformities of the external or middle ear. If the anomaly appears to be surgically correctable, identification of associated inner malformations is essential, since the anomaly may be inoperable. MRI studies can be used to directly evaluate the fluid spaces within the otic capsule.

Middle Ear and External Ear Malformations⁴¹

The most common anomaly of the middle ear and the external ear is *atresia* (also called *microtia*, or absence of the external ear) (Fig. 15–16).⁵⁵ Isolated anomalies of the ossicles can occur but are less common.

Figure 15-16. Atresia of the external auditory canal.

A, Axial CT scan showing a normal external auditory canal (EAC), middle ear, and oval window on the left. The right temporal bone is sectioned slightly more inferior in location and shows no external auditory canal. A thick bony plate completely covers the small middle ear cavity, centered at the cochlear promontory on the right.

B, Axial magnification view of the right ear. The deformed malleus is seen adjacent to the bony plate covering the EAC. The middle ear cavity is smaller than normal. The descending facial nerve is in a normal location. The mastoid air cells are well pneumatized.

C, Coronal CT scan showing a normal left EAC, internal auditory canal, and oval window. On the right, the otic capsule structures are intact but the EAC is completely replaced with thick bone. The descending facial nerve canal is somewhat anterior in location as it tracks toward the stylomastoid foramen.

Microtia may be associated with narrowing or agenesis of the bony external auditory canal. The degree of distortion can range from a web or small band of soft tissue partially covering the external auditory canal to complete absence.¹¹ Microtia is also associated with a number of other middle ear anomalies, including those seen in Pierre Robin and Apert's syndromes.

Numerous ossicular anomalies may be associated with atresia of the external auditory canal. The most common is fusion of the malleus and incus to the lateral epitympanic wall. Bony ankylosis of the neck of the malleus to the atresia plate is also common. Anomalies of the second branchial arch result in deformities of the long process of

the incus, stapes superstructure, and a portion of the footplate of the stapes. Combined ossicular anomalies are common. The stapes is most often involved in cases of isolated deformity.

The facial nerve canal must be carefully evaluated in all cases of suspected external and middle ear anomalies, particularly if surgery is planned, because anomalous development of the middle ear may alter the course of the facial nerve. In anomalies of the second branchial arch, the facial nerve canal may be positioned within the floor of the tympanic cavity or may cross the oval window. Occasionally, the facial nerve branches into two or three portions within the temporal bone.

Figure 15-17. Vestibular anomaly. *A*, Axial CT image at the level of the vestibule, epitympanic space, and cochlea. The ossicles and middle ear are normal. The cochlea is dysplastic. The vestibule is deformed with a bulbous configuration. The vestibule fuses with the lateral semicircular canal. The posterior semicircular canal is also enlarged. It is important to exclude an abnormal fistulous connection between an otic capsule abnormality and the middle ear. *B*, Coronal CT slice sectioned through the anomalous bulbous vestibule. The hypoglossal canal, superior semicircular canal, and occipital condyle are normal.

Inner Ear Malformations

Severe hearing loss secondary to malformations of the membranous labyrinth may coincide with entirely normal CT findings. A subtle finding associated with hearing loss is a lateral semicircular canal diameter less than 6 mm.⁴⁴ In contrast, some patients with CT evidence of minor dysplasias of the osseous labyrinth involving the cochlea, vestibule, or semicircular canals may have no clinical evidence of deafness.

The *Mondini malformation* is associated with hypoplasia, absence, or the presence of only a rudimentary coil of the cochlea. Generally, there is a central cavity that contains the remnants of the modiolus. The defect is usually bilateral and associated with dilatation of the vestibular aqueduct. More complex anomalies of the cochlea, with dilatation of the vestibule and partial or complete absence of the semicircular canals may also occur (Fig. 15–17).²

A complete lack of inner ear development is the *Michel defect*. A single labyrinthine cavity with no distinct vestibule, cochlea, or semicircular canals may be seen, or petrous development may be totally absent. Occasionally, the internal auditory canal is absent.^{19, 32}

CT evaluation of congenital inner ear malformations should include evaluation of the cochlear and vestibular aqueducts. In patients with large cochlear aqueducts, there is a high incidence of CSF leaks near the oval window (stapes “gusher” syndrome). There is a known association between cochlear abnormalities and dilatation of the vestibular aqueduct. Many patients with the Mondini or Michel malformation have enlarged vestibular aqueducts. This implies a deformity of the membranous labyrinth. Dilatation

of the vestibular aqueduct may also occur as an isolated event, leading to fluctuating hearing loss (Fig. 15–18).

Before placement of cochlear implants, patients are often studied with CT to more fully characterize the inner ear anomaly.⁶⁷ Following inflammation, the membranous labyrinth may be fibrotic and the cochlea may not accept the implant. There may be complete obliteration of the bony cochlea. MRI studies can confirm that the space within the bony otic capsule is filled with fluid when there is a question of fibrous obliteration of the otic capsule.

Vascular Anomalies

Many of the anomalies of the vascular structures of the temporal bone that were previously visible only on angiograms are now readily recognizable on high-resolution CT scans and MR images. If the surgeon is aware of the anomalous vasculature, vessel injury may be avoided during surgery or biopsy.

The development of the intrapetrous portion of the internal carotid artery is independent of that of the remaining ear. Because a vessel must be present before its canal forms, the carotid canal does not develop in cases of agenesis of the carotid artery. Agenesis of the intrapetrous carotid artery is thus identified on CT scans by absence of the carotid canal and carotid sulcus.

An ectopic intratympanic carotid artery (Fig. 15–19) may occur when there is alteration in carotid development.⁴⁴ The carotid canal may be partially absent, resulting in dehiscence of the bony margins and ectopic placement of the vessels into the middle ear. Pulsation tinnitus or conductive hearing loss, or both, may occur.² An intratym-

Figure 15–18. Giant vestibular aqueduct. This axial CT section is centered at the internal auditory canal and the lateral semicircular canal. The vestibular aqueduct is more than 2 mm in thickness. It is seen extending back toward the region of the vestibule and the common crus. Usually, the vestibular aqueducts are seen only as thin slits. This is a common congenital anomaly and suggests that other anomalies may be present, including those of the cochlea. The process may be bilateral as well.

Figure 15-19. Ectopic intratympanic carotid artery in a young adult presenting with a pulsating mass behind the right eardrum. *A*, Coronal CT scan of the right ear. There is a dehiscence (white arrowheads) in the floor of the tympanic cavity inferior to the cochlea. The ectopic carotid artery (black arrowheads) bulges into the hypotympanum through this bony dehiscence. *B*, Axial CT scan through the right hypotympanum. The vessel (arrow) simulates a soft tissue mass in the hypotympanum. The anterior lateral portion of the bony carotid canal is absent. (Courtesy of Dr. C. Roger Bird.)

panic, ectopic carotid artery may actually represent the inferior tympanic branch of the ascending pharyngeal artery secondary to agenesis of a segment of the internal carotid artery during early development. The aberrant vessel thus takes over as a source of blood flow to the brain. In either case, high-resolution CT or MRI studies can be used to differentiate these arterial vascular anomalies from a middle ear tumor. Angiography is generally not necessary but can be useful in questionable instances. On CT or MRI studies, the first genu of the ectopic carotid artery is usually located more lateral than normal and is abnormally tortuous. With dehiscence of the carotid canal, the carotid artery fills the anterior medial middle ear. The ectopic carotid artery is commonly small and tortuous. On angiography, the genu is lateral to the vestibule.

Another type of intratympanic vascular anomaly involves substitution of the stapedia artery for the middle meningeal artery. The intratympanic course of the stapedia artery is seen with enlargement of the tympanic portion of the facial nerve canal and absence of the ipsilateral foramen spinosum. Involvement of the facial nerve canal is seen in this defect because the development of the facial nerve canal closely parallels that of the middle meningeal artery. In this substitution anomaly, the stapedia artery originates from the intrapetrous internal carotid artery, runs with the facial nerve through the tympanic cavity, and then exits into the middle cranial fossa to supply the dura of the cerebral hemisphere.

Anomalies of the jugular vein and bulb are common. A defect in the bony plate separating the jugular bulb from the hypotympanum may result in a high jugular bulb that protrudes into the middle ear (Fig. 15-20). With other jugular bulb lesions, there is loss of the normal smooth margin of the osseous bulb because of irregular bony destruction.^{12, 17}

A high jugular bulb may also give rise to a jugular bulb

diverticulum (see Fig. 15-20). A diverticulum is distinct from a large jugular bulb because the diverticulum is usually posterior to the internal auditory canal and does not affect the middle ear.³ The diverticulum is recognizable on CT scans and should not be mistaken for a tumor.³⁴ MRI signal from slow flow in a diverticulum may mimic a mass. Two-dimensional gradient-echo or phase-flow images are particularly sensitive to slow flow abnormalities of the venous system.¹⁵

Inflammatory Lesions

Both CT and MRI are important in staging the primary changes and identifying complications of temporal bone inflammatory disease. CT has proved effective in detecting bony erosions and soft tissue masses associated with middle ear inflammatory disease. Contrast-enhanced MRI studies can be used to differentiate fluid and cholesteatoma from enhancing granulation tissue or tumor.⁴⁰

Acute and Subacute Otitis Media

Acute otitis media is associated with middle ear opacification.⁵⁶ Concomitant mastoiditis is evidenced by opacification or fluid levels in the mastoid air cells. The fluid in serous otitis media cannot be distinguished from the pus seen with purulent otitis. Subacute otitis media shows similar findings in the mastoid air cells and middle ear, with the additional finding of focal or diffuse mucosal thickening.

Chronic Otitis Media and Chronic Mastoiditis

Chronic otitis media (Fig. 15-21) results in the formation of granulation tissue that may become heaped up, obscuring the margins of the middle ear contents.⁶⁴ This

Figure 15–20. Dehiscent jugular bulb with diverticulum in an adult presenting with a pulsating bluish mass behind the left eardrum.

A and B, Coronal CT scans of the left ear. There is a dehiscence in the floor (*white arrowheads*) of the tympanic cavity, with extension of a portion of the jugular bulb (*black arrowheads*) into the hypotympanum (A). The remaining jugular fossa is sharply defined. A small diverticulum of the jugular fossa (*white arrow*) protrudes superiorly toward the roof of the petrous temporal bone (B).

C and D, Axial CT scans of the left ear. Note the dehiscence (*black arrowheads*) of the jugular fossa with extension of the jugular bulb simulating a mass into the hypotympanum (*white arrowhead*) (C). The diverticulum (*white arrow*) extends superiorly to the level of the osseous labyrinth (D). The ipsilateral sigmoid sinus impression is also large, suggesting a developmental variation rather than tumor.

Figure 15-21. Chronic otitis media in a young child with a long history of right-sided conductive hearing loss.

A and B, Coronal CT scans of the right ear. There is a soft tissue density within the tympanic cavity (arrows). The tympanic membrane is retracted medially. The ossicles are intact and show no evidence of bone destruction.

C and D, Axial CT scans of the right ear. The middle ear cavity is largely opacified. The sinus tympani is involved (arrow). The mastoid air cells are poorly developed. The nasopharynx should be evaluated to rule out an obstructive lesion. In children, the nasopharyngeal process is commonly an adenoid enlargement.

process results in areas of nondependent radiodensities within the middle ear. The tympanic membrane is usually retracted inward in patients with chronic otitis media. The mastoid may be poorly developed and sclerotic, since this process begins in childhood.

Chronic mastoiditis (Fig. 15-22) follows repeated bouts of otitis media and accompanying mastoid infections. There is a gradual reduction in the number of mastoid air cells, with thickening of the mucous membrane and reactive sclerosis of the bony septa. Persistent suppuration leads to mucosal destruction and subsequent granulation tissue formation. Erosion of mastoid air cell walls rarely occurs without the presence of cholesteatoma.

Cholesteatoma

Cholesteatomas develop in patients with chronic perforations of the tympanic membrane, usually from eustachian

tube dysfunction. Most perforations occur at the pars flaccida segment of the tympanic membrane (Fig. 15-23). Perforations of the pars tensa membranae tympani are rare. In these patients, the cholesteatoma extends directly into the central portion of the middle ear (Fig. 15-24).

Histologically, cholesteatomas consist of an inner layer of desquamated, stratified squamous epithelium apposed on an outer layer of subepithelial connective tissue. The subepithelial connective tissue layer is formed by a chronic inflammatory process that deposits cholesterol crystal clusters, giant cells, and round cells. Accumulation of epithelial debris within the lumen leads to progressive enlargement of the epithelial soft tissue mass. As the lesion enlarges, it contacts the contiguous bony structures of the middle ear, mastoid air cells, and petrous pyramid, causing erosion from pressure necrosis and enzymatic lysis of bone. Cholesteatomas typically originate in the middle ear but

Figure 15-22. Cerebritis and mastoiditis in a young man who presented with a seizure and left ear drainage. This coronal T2-weighted, high-resolution, spin-echo MR image demonstrates a region of edema related to brain infection in the inferior portion of the left temporal lobe. In the adjacent left temporal bone, there is opacification of the middle ear cavity due to septic mastoiditis. Note the small fluid collection (epidural) along the superior portion of the left temporal bone related to the infection. In patients with temporal lobe pathology, a careful review of the temporal bones should always be made to exclude an extra-axial source.

may extend into mastoid air cells and, occasionally, into the petrous pyramid.

Pus within a denuded mucosal cavity results in proteolytic erosion of the ossicles and walls of the middle ear. Chronic otitis media and cholesteatoma are thus characterized by a combination of focal or diffuse soft tissue densities in association with focal or diffuse bone destruction. This process leads to rarefying osteitis or erosive otitis media. The erosions typically involve the lateral wall of the tympanic cavity, including the scutum and the ossicles.²⁶ The facial nerve canal and lateral semicircular canal are rarely affected.²⁹ Differentiation from cholesteatoma may be impossible.

Classically, cholesteatomas expand into the antrum and mesotympanum, resulting in medial displacement of the ossicles away from Prussak's space. From the mesotympanum, the extension may be posterior into the sinus tympani or inferior into the hypotympanum. Further growth may be in several directions, most commonly into the posterolateral attic and then through the aditus into the antrum and mastoid air cells.⁵²

The diagnosis of cholesteatoma is based on the identification of a sharply demarcated soft tissue mass in the middle ear and bony destruction. Most of the time, the diagnosis is clear and is based on physical examination. The purpose of imaging is to stage the lesion. Continual

Figure 15-23. Epitympanic cholesteatoma in an elderly woman with a long-standing history of vertigo and left-sided hearing loss. A and B, Coronal CT scans of the left ear show a large, destructive soft tissue mass in the tympanic cavity, epitympanic space, attic, and antrum (arrows). The scutum is thinned. The walls of the middle ear cavity are expanded and amorphous. There is erosion of the cholesteatoma into the lateral semicircular canal. The tympanic membrane is retracted. The tegmen antri is thin, but there is no evidence of intracranial extension (arrowheads).

Figure 15-24. Inflammatory cholesteatoma.

A, Axial CT through the middle ear, which is largely opacified. The ossicles are partially destroyed and pushed anteriorly. The mastoid air cells are also opacified. There is no otic capsule destruction.

B, Coronal CT image through the oval window. The middle ear is almost completely opacified. The normal ossicular structures have been eroded. The epitympanic space is opacified as well. The mass does not protrude into the external auditory canal, but the scutum is blunted.

C, Coronal CT image centered at the geniculate ganglion. The distal limb of the geniculate ganglion canal is eroded by the middle ear mass.

Figure 15-25. Small early cholesteatoma. Coronal CT scan of the left temporal bone shows a small soft tissue mass (arrow) just lateral to the malleus and medial to the scutum. There is no bone destruction. This is consistent with an early deformity of the pars flaccida and a cholesteatoma.

pressure on the ossicles may lead to necrosis or dislocation. The most common type of ossicular destruction involves the short and long processes of the incus, followed by destruction of the body of the incus and the head of the malleus.⁵² Early small cholesteatomas (Fig. 15-25) may be associated with no bony change.

Patients with facial nerve palsy may have erosion of the facial nerve canal and compression of the facial nerve. Labyrinthine fistulas may form when there is erosion into the lateral or posterior semicircular canals. In rare instances, a cholesteatoma may extend into the otic capsule or the middle cranial fossa through the tegmen antri or tegmen tympani.

The cholesteatoma may be extruded spontaneously through an acquired osseous defect, usually associated with a large bony defect of the external auditory canal and mastoid (autoantrectomy) (Fig. 15-26).²⁸ Such an osseous defect may appear similar to a surgical defect. The residual cavity may have circumferential mural cholesteatomatous material, with an empty, air-filled central cavity.

Malignant External Otitis

Malignant external otitis (Fig. 15-27) is most often associated with a *Pseudomonas* infection in elderly, diabetic, or immunosuppressed patients. These patients complain of severe otalgia and purulent discharge from the external auditory canal.

More extensive disease causes necrosis of the adjacent soft tissues, with extensive bony destruction. The bony destruction may involve the walls of the external auditory canal and may extend into the tympanic cavity and inner ear, leading to hearing loss and facial nerve dysfunction.

The necrotizing soft tissue infection may also spread along Santorini's fissures (small clefts in the cartilaginous portion of the external auditory canal) into the soft tissues of the nasopharynx and oropharynx. Both the osseous and soft tissue spread may lead to intracranial extension. If left untreated, the disease progresses, leading to meningitis, cerebritis, and osteomyelitis of the skull base. The disease can be fatal in a short period, thus earning the term *malignant external otitis*.

Figure 15-26. Autoantrectomy. Axial CT section through the right superior temporal bone. There is a large defect in the mastoid with thinning of the bony margins (arrowheads). A central soft tissue mass partially fills the space. This patient did not have surgery, but the cholesteatoma has almost completely emptied the mastoid space as a result of chronic bone destruction. There is erosion of the superior semicircular canal (arrow).

Early findings include soft tissue thickening of the external auditory canal with clouding of the middle ear and mastoid air cells. There are varying degrees of surrounding bone destruction involving the temporomandibular joint, petrous pyramid, tympanic cavity, or mastoid process.

CT scanning with IV contrast material is needed to define the extent of disease within the soft tissues of the head and neck. There may be widespread enhancement with multiple focal abscesses. CT and MRI studies optimally demonstrate the fat and muscle planes, illustrating the extent of the disease in the soft tissues of the pinna, parapharyngeal space, clivus, infratemporal fossa, and carotid sheath.¹¹ Involvement of the subtemporal fossa is evidenced by obliteration of the normal fat planes, whereas involvement of the parapharyngeal space is evident by loss of the characteristic CT low density within the space and presence of a mass lesion.¹⁸ Marrow involvement and vessel occlusion are best seen on MR images.

CT is excellent for following the progression of the bone and soft tissue involvement after treatment. The bone erosions are usually constant. If there is no resolution after appropriate antibiotic therapy, surgery may be necessary for adequate drainage of soft tissue abscesses and removal of destroyed bone.⁴²

Infection of the Endolymphatic Sac

MRI is sensitive to subtle changes of the membranes of the otic capsule structures. Transient enhancement may commonly involve the vestibule (Fig. 15-28) and is generally thought to represent a viral infection or another inflammatory process. In rare instances, enhancement of the endolymphatic duct and cochlea is seen. Suppurative infections (e.g., syphilitic, staphylococcal) produce enhancement as well, but the findings are more persistent. These infec-

Figure 15-27. Malignant external otitis.

A, Coronal CT section through the external auditory canals. There is slight loss of the fatty interfaces surrounding the soft tissue portion of the right external auditory canal. The bulk of the pathology is centered in the parapharyngeal space and the nasopharynx. There is obliteration of the normal fat planes in the infratemporal fossa and an ill-defined soft tissue mass (*arrowheads*).

B, Coronal T1-weighted MRI study at a similar location. The fat planes directly parallel to the right external auditory canal (*white arrow*) are partially obliterated. The fatty marrow spaces of the clivus (*black arrowheads*) and the adjacent fatty soft tissue space (*white arrowheads*) have been replaced by lower-signal inflammatory tissue. The ascending internal carotid artery is enveloped by these infiltrative changes.

(**A** and **B**, Courtesy of Barbara Carter, M.D.)

Figure 15-28. Endolymphatic sac inflammation in a young male who presented with severe hearing loss and vertigo, probably related to a viral infection. This is an axial 3D Fourier transform T2-weighted, high-resolution MR image through the descending facial nerve and the lower endolymphatic duct. Note the abnormal enhancement of the sac. Unlike a congenital anomaly or a tumor, the sac is not enlarged. This type of finding suggests an inflammatory process and has been described in association with Meniere's disease.

tions demonstrate other more aggressive findings such as bone destruction and mass effect. Occasionally, sarcoid, metastasis, lymphoma, or eosinophilic granuloma may mimic an infection early in their course.^{33, 51, 65}

Brain Abscess

Brain abscesses may develop from temporal bone inflammatory processes by several mechanisms. Petrositis of the apical air cells can extend into the epidural and skull base spaces. In these instances, CT scanning shows the bony destruction with dural enhancement adjacent to the temporal bone. This is called *Gradenigo's syndrome*. Cholesteatomas can erode through the tegmen tympani or tegmen antri into the middle cranial fossa or through the mastoid into the posterior cranial fossa. CT or MRI with contrast enhancement shows elevation and enhancement of the dura with extension of pus into the epidural space (see Fig. 15–22). Classic ring-enhancing lesions can also be seen. In patients with recurrent cholesteatomas after radical mastoidectomies, intracranial spread of the infection may develop. This occurs when the bony barriers have been surgically removed.

Meniere's disease is a poorly understood disorder of the temporal bone consisting of intermittent severe vertigo with progressive hearing loss. Some believe that it is related to inflammation of the membranes of the otic capsule leading to obliteration of the endolymphatic duct. In the active phase, enhancement of the endolymphatic sac may be seen. Later on, the endolymphatic sac may be asymmetrical or not visible. The imaging diagnosis is complicated by the fact that there are many variations in the sacs among patients and from side to side in the same patient.⁶⁶

Neoplastic Lesions

Benign Neoplasms

Osteomas

Osteomas (Fig. 15–29) are common benign tumors of the temporal bone. Some osteomas are large enough to occlude osseous foramina such as the external auditory canal or the eustachian canal. Osteomas may also develop in the mastoid process after trauma. Bony thickening of the external auditory canal is commonly associated with prolonged exposure to cold water and is usually seen in swimmers. CT scanning demonstrates an osteoma as an area of dense thickening of compact bone.

Acoustic Schwannomas

Acoustic schwannomas are benign tumors of cranial nerve VIII, usually located within the internal auditory canal and cerebellopontine angle cistern. They classically arise at the junction of the neuroglial and Schwann cell sheaths, commonly near the porus acusticus. The vestibular nerve is the most common site of origin.

Symptoms are directly related to the size and location of the tumor. Growth of acoustic schwannomas in the internal auditory canal causes compression of the cochlear and vestibular nerves. This results in progressive neurosensory loss and tinnitus. Early vestibular dysfunction is uncommon, probably resulting from the slow growth of the

Figure 15–29. Osteoma of the left external auditory canal (EAC) in a 13-year-old boy with a history of cold-water swimming and a chronic deformity of the EAC. Coronal (A) and sagittal (B) reformatted CT images through the left EAC. The EAC is opacified, with osseous constriction of its medial portion. The osteoma (arrowheads) is completely incorporated into the adjacent bone (A). Note the keyhole constriction (arrowheads) of the EAC, best seen in the sagittal reformatted image (B). Within the stenotic EAC is a soft tissue mass that represents a secondary EAC cholesteatoma.

tumor, which allows for central compensation of the progressive peripheral dysfunction.²³ Facial nerve paresis or palsy is a rare event but may occur with large masses. Clinical symptoms from the fifth cranial nerve are actually more common than the seventh cranial nerve.

The imaging presentations of acoustic schwannomas vary widely. Some of these tumors are only a few millimeters in dimension (Fig. 15–30), and are difficult to identify, whereas others are so massive (Fig. 15–31) that they are life-threatening. They rarely occur within the vestibule or cochlea (Fig. 15–32). Some tumors cross from the internal auditory canal into the otic capsule regions, but this is uncommon.

CT scans can be used in diagnosis, as large tumors can be seen directly. Small tumors of the internal auditory canal that do not affect the bony margins necessitate either air-contrast cisternography or MRI studies. The bony changes of the internal auditory canal, porus acusticus, and otic capsule are common and help to differentiate acoustic tumors from other cerebellopontine angle masses (Fig. 15–33).⁵⁸ It is extremely uncommon for a nonacoustic tumor to expand or to erode the auditory meatus. Asymmetry of the internal auditory canals of more than 2 mm suggests the presence of a mass. IV contrast enhancement may

Figure 15-30. Small right acoustic schwannoma.

A, Axial T1-weighted, 3D Fourier transform, contrast-enhanced MR section through the internal auditory canal (IAC). The posterior portion of the IAC is filled with a small enhancing mass, which does not protrude into the cerebellopontine angle (CPA). There is some remodeling of the posterior margin of the IAC. Other structures depicted include the fourth ventricle, basilar artery, and sixth cranial nerve.

B, Axial T2-weighted, 3D Fourier transform, high-resolution, gradient-echo, non-contrast-enhanced image at a site similar to that in A. The seventh and eighth cranial nerves are seen in the CPA and the IAC. There is a small posterior filling defect related to the small tumor. The more lateral segments of the cranial nerves in the IAC are visible.

Figure 15-31. Large acoustic schwannoma. Axial T1-weighted, contrast-enhanced, spin-echo MRI study shows a large, lobulated left anterolateral posterior fossa mass (arrowheads). The lesion enhances inhomogeneously. A medial cyst is adjacent to the lesion (arrows). The acoustic schwannoma displaces the fourth ventricle (fv) to the right. There is massive erosion of much of the medial temporal bone, with replacement by schwannoma.

Figure 15-32. Vestibular schwannoma in a patient presenting with symptoms suggesting an acoustic schwannoma; however, no lesion was seen in the internal auditory canal (IAC).

A, Axial contrast-enhanced, high-resolution, 3D Fourier transform, T1-weighted MR image through the vestibule and the IAC. The normal eighth cranial nerve is seen in the IAC. There is abnormal enhancement of the normal-sized vestibule. This was able to be seen with vestibulitis, but this finding did not resolve in a few weeks. The imaging properties of an otic capsule schwannoma are identical to those in the IAC, but the location is different.

B, MR scan made at the same level as in **A** but with a high-resolution, 3D Fourier transform, gradient-echo, T2-weighted MR sequence. Again, the IAC and the eighth cranial nerve are normal. A filling defect is seen where the enhancing mass was centered on the contrast study. Filling defects are more likely to be tumors than inflammatory changes.

Figure 15-33. Neurofibromatosis type 2.

A, Axial T2-weighted, 3D Fourier transform, high-resolution, gradient-echo MR image acquired through the internal auditory canals. Filling defects are seen in both internal auditory canals (IACs). The mass on the right is larger and extends out into the cerebellopontine angle. Bilateral acoustic tumors suggest neurofibromatosis type 2 or carcinomatosis. No other meningiomas or neuromas are seen on this section, but they should be sought.

B, Axial T1-weighted, 3D Fourier transform, high-resolution, gradient-echo MR image acquired after contrast through the IACs. Both tumors of the IACs are seen as enhancing small masses. The mass on the right shows greater enhancement.

reveal a classic mushroom-shaped mass centered at the internal auditory canal.

Massive tumors (see Fig. 15–31) may cause severe distortion of the posterior fossa, with brain stem herniation, hydrocephalus, and displacement and compression of the fourth ventricle. Some acoustic schwannomas can be cystic. Bilateral acoustic schwannomas are associated with neurofibromatosis type 2 (Fig. 15–34; see Fig. 15–33).

In general, MRI is better than CT in the diagnosis of acoustic schwannomas. Enhancement and enlargement of the eighth cranial nerve within the internal auditory canal (or even the otic capsule) can be seen. Small lesions are visible on survey examinations without the need for cisternography. MRI can differentiate small acoustic tumors from the nerves themselves. Smaller tumors can be seen to displace the nerves in the internal auditory canal. The nerve can be seen crossing small tumors. This is important for surgical planning and usually implies a better prognosis for hearing salvage after surgery. Larger tumors totally fill the internal auditory canal and obscure the other anatomic structures. The other characteristic findings of larger tumors can also be appreciated. Careful review of other cranial nerves is important to rule out neurofibromatosis.

The rate of growth of acoustic schwannomas is variable. Accurate follow-up is important because many tumors do not grow and may not warrant therapy, particularly in the case of older patients. High-resolution imaging is essential to aid in recognition of subtle changes in tumor volume.

Better evaluation of these tumors is more important now that there are many different management possibilities, including waiting, surgery, and focused radiation.

Facial Nerve Schwannomas

Facial nerve schwannomas (Figs. 15–35 and 15–36) may be located anywhere along the course of cranial nerve VII. These tumors are gray, firm, lobulated masses that may be either schwannomas or neurilemmomas. Both originate from Schwann cell sheaths. These tumors most frequently involve the geniculate ganglion and tympanic mastoid portions of the facial nerve. Although facial schwannomas are commonly associated with facial nerve palsy, they account for only about 5% of all peripheral facial palsies. Inflammation (Bell's palsy) (Fig. 15–37), trauma, infection, and neoplasm are more common causes of cranial nerve VII dysfunction.²²

The location of the schwannoma determines the constellation of clinical findings. Neurosensory hearing loss resulting from compression of adjacent cranial nerve VIII is seen with cerebellopontine angle and internal auditory canal tumors or erosion into the cochlea. Conductive hearing loss may be seen in tympanic cavity schwannomas associated with ossicular dysfunction.

Although the CT findings of an intracanalicular or cerebellopontine facial schwannoma are similar to those of acoustic schwannomas, erosion of the anterosuperior por-

Figure 15–34. Bilateral acoustic schwannoma in a young female with a history and the stigmata of neurofibromatosis.

A, Coronal noncontrast, T1-weighted MRI study shows bilateral lobulated smoothly margined masses in the cerebellopontine angles. The mass on the right (*arrowheads*) expands the internal auditory canal. The mass on the left is circular and isodense and is in the cerebellopontine angle (*arrows*).

B, Axial T2-weighted section superior to the internal auditory canals. There is enlargement of the right fifth cranial nerve (*black arrowheads*) and filling of Meckel's cave by a neurofibroma of the trigeminal nerve (*white arrowheads*). There is also thickening of the proximal portion of the left fifth cranial nerve (*white arrow*). A nearly isointense mass at the surface of the lateral hemisphere relating to meningioma can also be seen (*black arrows*).

Figure 15-35. Facial schwannoma.

A, Axial CT image of the right temporal bone in a patient presenting with a long history of facial palsy that did not improve. The lateral internal auditory canal (IAC) is expanded. There is a broad opening of the IAC and the geniculate ganglion related to the schwannoma. There is erosion of the bone facing the middle cranial fossa.

B, Axial CT image, slightly inferior in relation to A. The geniculate ganglion is clearly expanded, with erosion of the anterior portion of the facial canal. This type of pattern can be seen with a hemangioma or with perineural spread of tumor.

Figure 15-35 *Continued C*, Coronal CT image through the geniculate ganglion region. Note the massive enlargement of the canal superior and medial to the cochlea and carotid canal. The bony canal is smoothly enlarged, a common finding with facial schwannomas and acoustic schwannomas. The location of the bony expansion is centered anteriorly and superiorly in the IAC and along the facial nerve canal.

tion of the internal auditory canal and the geniculate ganglion region in particular may distinguish proximal facial schwannomas from acoustic schwannomas.³¹ Tumors originating within the facial nerve canal cause enlargement and erosion of the involved segment.⁶¹ Extracanalicular expansion of schwannomas may be evidenced by eccentric location of the tumor mass beyond the facial nerve canal, in the supralabyrinthine area, the middle ear cavity, the mastoid segment, or the parotid gland. Involvement of the geniculate ganglion is easy to detect on CT scans because of enlargement of the geniculate fossa on axial images. Most of these tumors enhance on MRI studies and have a characteristic tubular shape following the complex curves of the nerve.

Meningiomas

Most meningiomas (Fig. 15-38) arise outside the middle ear from the meninges covering the posterior petrous bone. Some meningiomas may subsequently invade the temporal bone, producing primarily otologic symptoms. Meningiomas arising within the cerebellopontine angle cause varying symptoms, including deafness, tinnitus, posterior fossa herniation, and facial paresis, although most are not symptomatic until they are large, in contrast to most acoustic

schwannomas. Meningiomas rarely originate within the internal auditory canal. When this does occur, it may simulate an acoustic tumor with vestibular and otologic symptoms. In a few instances, meningiomas may arise from ectopic arachnoid granulations within the middle ear cleft.⁶³ They may also be seen in neurofibromatosis.

Meningiomas of the cerebellopontine angle are classically semicircular dura-based lesions that protrude posteriorly. On CT scans, some are partially calcified and usually enhance. Hyperostosis of the posterior margin of the temporal bone is difficult to recognize because it is already highly dense, but air spaces changes are more sensitive. The internal auditory canal is usually not affected, or it is covered. Large lesions deform the adjacent brain and tract along the adjacent dural (Meckel's cave, petroclinoid ligament) structures.

On MRI studies, the lesions may be isointense with brain without contrast. The junction of the meningioma and temporal bone usually forms an obtuse angle, whereas an acoustic schwannoma usually forms an acute angle with the temporal bone.¹⁷ In rare circumstances, the meningioma involves the mastoid and middle ear structures, either as en bloc cerebellopontine angle lesions or arising centrally without a dural surface involved. On CT scans, sclerosis

Figure 15-36. Facial schwannoma in a woman with a history of slowly progressive left facial paralysis.

A, High-resolution axial CT scan of the skull base through the internal auditory canals. The left distal limb of the geniculate ganglion and the horizontal facial nerve canals are enlarged (*black arrowheads*). There is opacification of the middle ear and mastoid.

B, Axial section, inferior in relation to **A**, at the level of the external auditory canal. The left descending facial nerve canal (*black arrow*) is much larger than the right (*black arrowhead*).

C, Coronal T1-weighted, contrast-enhanced MRI section paralleling the descending facial nerve. The nerve (*white arrowheads*) is enlarged and enhances, and there is also a component within the middle ear (*black arrow*). This pattern (tumor following the convoluted course of the facial nerve) is characteristic.

(A–C, Courtesy of Dr. Charles Lanzieri.)

Figure 15-37. Bell's palsy in a middle-aged woman who presented with acute left facial palsy that gradually improved. This axial T1-weighted, contrast-enhanced MRI study shows linear enhancement of the seventh cranial nerve within the internal auditory canal (*white arrowhead*) and the horizontal portion of the facial nerve (fallopian) canal (*white arrow*). The seventh and eighth cranial nerves are easily seen in the cerebellopontine angle on the right (*black arrows*). There is no enlargement of the canal or bone destruction. (Courtesy of Theodore Larson, M.D.)

Figure 15-38. Meningioma in a middle-aged woman with multiple lower left cranial nerve deficits. **A**, Steeply angled axial CT scan of the skull base after contrast infusion. A large, enhancing, dura-based mass extends along the clivus and the left petrous bone. The tumor mass contains scattered calcifications. The adjacent brain structures are extensively deformed. **B**, High-resolution CT image at same level as in **A**. There is extensive sclerosis of the left petrous bone with partial opacification of the mastoid air cells.

and soft tissue opacification may be seen. On MRI studies, the infiltrative tumor may enhance.

Paragangliomas (Glomus Tumors)

Paragangliomas (Figs. 15-39 and 15-40), also referred to as *glomus tumors*, are slow-growing, purple-red vascular tumors that arise from chemoreceptor cells.^{12, 62} They are histologically related to pheochromocytomas, are of mesenchymal or neuroectodermal origin, and secrete catecholamines in approximately 10% of instances. Arising from the ninth and tenth cranial nerves, paragangliomas are the most common tumor of the middle ear and the second most common tumor of the temporal bone after acoustic schwannoma. They occur most frequently in middle-aged women. They may be multicentric in up to 10% of patients and are commonly familial.²² Even though most of the paragangliomas are benign and solitary, they are locally highly aggressive, simulating a malignant tumor in their local behavior. Some are malignant and metastasize.

Histologically and biologically, the lesions are similar, but historically they have unique names associated with their locations. Glomus tumors (paragangliomas) typically develop in the jugular bulb (glomus jugulare), the middle ear (glomus tympanicum), the carotid body (carotid body tumor), and the ganglion of the vagus nerve (glomus vagale).¹² Jugulotympanic glomus tumors involve both the middle ear and jugular bulb.

Symptoms are based on the location and size of the tumor. Tumors of the middle ear typically cause pulsating tinnitus, with subsequent conductive hearing loss. Paragangliomas cause permeative bone destruction; surprisingly, however, they often spare the ossicles. Erosion of the promontory or invasion into the cochlea leads to progressive neurosensory hearing loss. Vertigo may accompany the hearing loss as the tumor advances into the labyrinth. Involvement of the facial and lower cranial nerve canals may result in cranial nerve dysfunction. Extension superi-

orly into the middle cranial fossa may occur as the tumor erodes the tegmen. Because many of the tumors arise within the jugular fossa, extension intracranially or inferiorly into the upper neck with venous occlusion is common. Most posterior cranial fossa involvement is extradural. A nodular appearance of the medial intracranial border indicates intradural extension.⁶²

Differentiation of these lesions is usually not possible by otoscopy alone unless the glomus tympanic mass is small enough so that its circumference is visible.³⁵ High-resolution cross-sectional imaging is effective in staging these tumors. Vascular anomalies as well as some other nonvascular lesions in the differential diagnosis may be accurately assessed by CT and MRI studies. Angiography is still important in their evaluation. Differentiation of paragangliomas from vascular malignant tumors (renal cell metastasis) may be difficult.

Glomus tympanicum tumors (see Fig. 15-39) are isolated to the middle ear cavity. They usually arise on the cochlear promontory and extend into the middle ear and mastoid air cells. The most common CT finding is the presence of a small soft tissue density protruding from the cochlear promontory without bony destruction.^{12, 45} CT and MRI studies with IV contrast agents demonstrate a homogeneous, densely enhancing soft tissue mass within the tympanic cavity. These tumors may also fill the middle ear cavity but rarely cause ossicular destruction. The highly vascular nature of the lesions can be confirmed with angiography.

Glomus jugulare tumors (see Fig. 15-40) show bony destructive distortion at the separation of jugular fossa and hypotympanum.¹² The tumors commonly invade the hypotympanum. There may be displacement of the tympanic membrane and the long process of the malleus and erosion of the basal turn of the cochlea. On CT scans, invasion into the infralabyrinthine compartment results in a mottled appearance.⁶² Infralabyrinthine involvement may

Figure 15-39. Glomus jugulare paraganglioma in a patient presenting with pulsatile tinnitus.

A, Axial CT image through the basal turn of the cochlea. A small, hypotympanic, soft tissue mass in the middle ear overlies the cochlear promontory. The adjacent temporal bone is eroded near the jugular fossa. The erosion is very near the descending facial nerve canal. This combination of a destructive mass arising near or in the jugular fossa and extending into the middle ear is characteristic of paragangliomas.

B, Axial CT section, slightly superior in relation to A, shows the mass in contact with the round window, the long process of the malleus, the long process of the incus, and the tympanic membrane. There is no destruction of the ossicles, which is typical. There is some minor opacification of the mastoid.

Figure 15-39 Continued C, Lateral angiogram of the internal maxillary artery showing enlargement of the many feeding vessels (including the ascending pharyngeal artery) extending to the jugular fossa. The highly vascular tumor is characteristic of a paraganglioma.

destroy the vertical and horizontal portions of the carotid canal. In these patients, preoperative balloon occlusion of the carotid artery may be necessary. The examination should extend inferiorly to include the upper neck, and intracranially, since these tumors commonly follow the jugular venous system from the torcular Herophili to the lower cervical jugular vein. On MRI studies, the vascular nature of the lesion is demonstrated by the presence of small tortuous signal voids.

Angiography is still important in the preembolization workup to define various vascular pedicles so that each pedicle can be individually catheterized and embolized. Catheter or magnetic resonance venography may be needed to confirm the patency of the venous structures.

Epidermoidomas (Epidermoid Cysts)⁴⁹

Epidermoidomas (*primary congenital cholesteatomas*) consist of masses of embryonic ectodermal rests and are thus distinct from true cholesteatomas, whose formation is a reaction to inflammation and trapped squamous epithelium. These lesions may be found in several areas within the temporal bone. They can arise in the external auditory canal, leading to chronic obstruction (Fig. 15-41), termed *keratosis obturans*. Some lesions originate in the middle ear, with subsequent erosion of the ossicles, facial nerve

canal, or lateral semicircular canal. Patients usually have unilateral serous otitis or unexplained unilateral conductive hearing loss. Some epidermoidomas originate in the osseous structures, typically in a supralabyrinthine location. The lesions show sharp outlines with distinct edges and appear as expansile cystic lesions along the superior portions of the temporal bone.

Typically, the lesions exhibit a “punched-out” appearance. They may erode into the facial nerve canal or internal auditory canal, causing facial nerve palsy or hearing loss. They may also arise in the petrous apex, forming an expansile, sharply margined destructive lesion that can affect the clivus (Fig. 15-42).

Epidermoidomas may also originate in the cerebellopontine angle. These masses can demonstrate a wide range of imaging characteristics. On CT scans, they are frequently low density structures and may mimic a subarachnoid cyst. They can be solid or even calcified and usually do not significantly enhance. Contrast cisternography characteristically shows a frondlike pattern as the contrast enters many small channels at the irregular surface of the lesion. On MRI scans, a wide range of findings may also be seen, including expansion out of the cerebellopontine angle into Meckel’s cave or the ambient cistern. These tumors do not tend to invade the brain.

Figure 15-40. Glomus jugulare in a 40-year-old woman presenting with multiple lower cranial nerve palsies and a visible blue middle ear mass.

A, Magnified axial CT scan of the left temporal bone through the hypotympanum. The left jugular fossa is massively enlarged (black arrowheads) with destructive margins. A mass extends into the petrous apex. A thin margin of bone outlines the carotid canal (white arrowheads). The separation of the mass and the middle ear is poorly defined.

B, Sagittal non-contrast-enhanced, T1-weighted MR image through the jugular fossa. The jugular fossa is usually seen as a signal void as a result of cortical bone and blood flow. In this instance, a low-signal-intensity soft tissue mass is seen expanding the jugular fossa (white arrowheads) but does not extend through the dura.

Hemangiomas of the Facial Nerve

Small hemangiomas of the facial nerve are actually as common as facial schwannomas. These benign tumors most commonly affect the geniculate ganglion, but they occasionally involve the internal auditory canal. Patients usually present with progressive facial paralysis. Most of these tumors are not extremely vascular but, instead, are partially calcified. On CT scans, one sees a small lesion of mixed sclerosis with erosion of the facial nerve canal. On MRI studies, hemangiomas may display slight contrast enhancement (Fig. 15-43).

Miscellaneous Benign Lesions

A variety of neoplastic and non-neoplastic lesions occasionally involve the cerebellopontine angle and the temporal bone. Other cranial nerve tumors may occur in addition to acoustic schwannomas.

Trigeminal schwannomas typically follow the course of the nerve from the anterior pons into Meckel's cave and then into the subtemporal fossa.³ The foramen ovale and rotundum as well as the superior orbital canal may be enlarged.

Schwannomas of lower cranial nerves IX, X, XI, and XII may mimic paragangliomas by forming a dumbbell-shaped mass that enlarges the jugular fossa (Fig. 15-44).¹² On angiograms, however, they are often less vascular.

Lipomas and some epidermoid or dermoid tumors of the cerebellopontine angle may be readily identified by CT as low-density fatty masses.²¹ On MRI studies, if the masses are composed predominantly of triglyceride, they

Figure 15-41. Epidermoid of the external auditory canal in a young man presenting with a chronic history of bilateral external canal obstruction. He had no history of chronic infection or tympanic membrane rupture (as would be seen with cholesteatoma). The axial CT scan through the right external auditory canal (eac) shows a smoothly marginated mass (arrowheads) expanding the canal. The mastoids and protympanum are intact without inflammatory changes.

Figure 15-42. Epidermoid of the petrous apex in a 40-year-old man presenting with symptoms similar to those of an acoustic schwannoma. *A*, Axial CT image through the left internal auditory canal shows a large destructive lesion (arrows) involving the petrous apex, internal auditory canal (iac), and cochlea (c). The lesion is rather sharply margined. The mastoid and middle ear are intact. *B*, Axial T2-weighted MR image demonstrates that the lesion has a very high signal (consistent with a high water content). One component is within the petrous apex (arrows), and a second larger area involves the anterior portion of the middle cranial cavity (arrowheads). There is little reaction of the adjacent brain.

Figure 15-43. Facial nerve hemangioma in a patient with slowly progressive facial paralysis. The axial CT section through the left temporal bone shows mixed sclerosis and destruction of the geniculate ganglion region (arrowheads). The normal smoothly margined canal is not visible and is replaced with an irregular cluster of calcification. There is no soft tissue component within the middle ear.

may have high signal intensity on T1-weighted images and may demonstrate chemical shift artifacts. If the fat is not triglyceride in nature, it appears as a low-density mass on CT scans but not as a high-signal-intensity mass on T1-weighted MR images.

Several non-neoplastic lesions may appear similar to their neoplastic counterparts. An *arachnoid cyst* of the posterior fossa can mimic a cystic cerebellopontine angle tumor (epidermoid). The CT appearance is that of a CSF-density mass filling the cerebellopontine angle cistern, with slight distortion of the adjacent brain structures. Scalloping of the petrous bone suggests a chronic process. It may be difficult to differentiate cystic epidermoids and dermoids from arachnoid cysts unless there is evidence of arachnoiditis. MRI is superior to CT in its capacity to help confirm the nature of cystic lesions.

Cholesterol granulomas of the petrous apex (Fig. 15-45) are slow-growing collections of blood products. These lesions are non-neoplastic. The etiology is not clear but may be related to chronic obstruction. These granulomas are common incidental findings on MRI studies that are seen as high-signal-intensity regions of subacute hemorrhage on all pulse sequences involving the petrous apex. There may be no expansion, and the CT findings are essentially normal. A minority of these lesions expand to erode the petrous apex. Most patients present with symptoms similar to those of an acoustic schwannoma. CT scanning typically shows a circular soft tissue density mass expanding the apex. There may also be involvement of the clivus and internal auditory canal. On MRI studies, the lesions are seen as expansile high-signal-intensity masses centered in the petrous apex.

Figure 15-44. Jugular fossa schwannoma in a teenaged girl thought to have neurofibromatosis and who presented with a recurrent jugular fossa schwannoma.

A, Axial contrast-enhanced, T1-weighted, spin-echo MRI study at a level inferior to that of the internal auditory canal. A large, lobulated, enhancing mass (arrowheads) is centered in the left jugular fossa region. The bony margins are eroded. The mass protrudes into the posterior fossa.

B, Sagittal, non-contrast-enhanced, T1-weighted MRI study through the jugular fossa. The slightly low-signal-intensity posterior fossa mass (arrowheads) extends from the cerebellum through the expanded jugular fossa into the superior neck. The adjacent internal auditory canal (arrow) is intact.

Malignant Neoplasms

Primary malignant neoplasms of the temporal bone are relatively uncommon. When they do occur, they are most often squamous or basal cell carcinomas. These tumors usually originate from mucosal epithelium of the external auditory canal, middle ear, or mastoid air cells and are usually aggressive. Patients who have primary squamous cell carcinomas of the external auditory canal may have a history of chronic external otitis. Symptoms may also include otalgia, bleeding, otorrhea, dizziness, deafness, and facial nerve palsy. They may extend locally into the parotid gland and the temporomandibular joint. More medial invasion is associated with a worse prognosis. Lymphatic invasion and subsequent distant metastasis are rare.

The most important CT finding suggesting a diagnosis of carcinoma is erosion of the walls of the bony external auditory canal or middle ear by a soft tissue mass in a patient who does not have a history of cholesteatoma.⁴⁶ CT scanning can outline the bony erosion and can show the extension of the soft tissue mass into the adjacent normal soft tissues.^{28, 64} On MRI studies, there may be edema and abnormal soft tissue with irregular enhancement after IV contrast infusion as well as distortion of the surrounding soft tissue planes (Fig. 15-46). In some patients, it is difficult to differentiate between tumor and secondary infection (malignant external otitis) because in both cases there may be soft tissue enhancement with the presence or absence of bony erosion.

Glandular neoplasms, such as adenoma and adenocarci-

noma, account for about 14% of primary temporal bone masses. The clinical and CT findings of glandular carcinoma are similar to those of squamous cell carcinomas, except that metastasis to regional lymph nodes may occur. For this reason, the lymph nodes at the skull base and upper neck should be evaluated on CT scans. Lymph node involvement is evidenced by peripheral soft tissue enhancement with central necrosis on IV contrast-enhanced CT studies.¹¹

Embryonal rhabdomyosarcoma (Fig. 15-47) is the most frequently encountered malignant middle ear neoplasm in children. Involvement of the temporal bone by rhabdomyosarcoma is relatively common. The tumor is highly aggressive, and bone destruction associated with a middle ear soft tissue mass occurs quite often. The patient may also have cranial nerve deficits. Intracranial spread secondary to direct epidural extension may be seen on CT or MRI studies as an enhancing mass in continuity with the ear mass. CT scanning is the ideal examination for monitoring recurrence after surgical resection, radiation, or chemotherapy.²² Eosinophilic granuloma may have a very similar appearance.

Malignant tumors from adjacent structures may secondarily involve the temporal bone from several avenues, including through the foramina and fissures of the skull base and from the soft tissues of the external auditory canal. The most common extensions are from nasopharyngeal cancer (Fig. 15-48) and skin and salivary gland cancers, via the eustachian canal and external auditory canal,

Figure 15-45. Cholesterol granuloma in a patient presenting with symptoms similar to those of an acoustic schwannoma.

A, Axial CT section through the right external auditory canal (eac) and carotid canal (cc). A large expansile mass is in the petrous apex. The margins of the surrounding bone are thinned. There is remodeling of the sphenoid sinus and the posterior margin of the temporal bone (black arrowheads). The mastoid is opacified. The external auditory canal is intact.

B, Axial T1-weighted, non-contrast-enhanced MRI study at the same level as in A. A large mass with very high signal intensity caused by subacute hemorrhage can be seen (arrowheads). The margins of the lesion are smooth, with displacement of adjacent structures rather than invasion. The lesion is centered at the petrous apex and involves the clivus. This lesion was of high signal intensity on all imaging sequences.

(A and B, Courtesy of William Lo, M.D.)

Figure 15-46. Basal cell carcinoma of the external auditory canal. **A,** Axial CT section through the left external auditory canal shows a soft tissue mass (black arrowheads) filling the canal and middle ear. Irregular destruction and expansion of the bony canal are shown. **B,** Coronal T1-weighted MRI study shows a large mushroom-shaped mass (white arrowheads) extending external from the auditory canal to involve the adjacent soft tissues. The normal fatty structures have been invaded.

Figure 15-47. Rhabdomyosarcoma in a 5-year-old girl who presented with rapidly progressive pain and swelling of the left mastoid, mimicking an acute infection. Biopsy showed an invasive rhabdomyosarcoma.

A, Axial bone window CT scan made through the internal auditory canals. The right ear is normal. The left ear shows a large destructive lesion (*black arrows*) involving the mastoid, external auditory canal, and middle ear.

B, Axial contrast-enhanced, T1-weighted, spin-echo MRI study at approximately the same level as in **A**. A large, enhancing soft tissue mass (*black arrows*) extends laterally from the region of bone destruction. There is secondary edema and thickening of the soft tissues overlying the calvarium on the left.

respectively.²³ Perineural spread occurs when malignant tumors track along the course of normal nerves (Fig. 15-49). This is a very subtle but important finding, since the tumor may appear to spread in a discontinuous manner and to recur a long distance from the primary site. This is most frequently seen with squamous cell cancer because it is the most common head and neck malignancy. Perineural spread is especially prevalent with adenoid cystic carcinoma and lymphoma. The facial nerve is most often affected. Perineural spread through the facial nerve can arise from tumors involving the parotid region or from small interconnecting branches of the fifth cranial nerve.²⁰

CSF carcinomatosis is a relatively common complication of systemic cancers (Fig. 15-50). The metastases can occur in the internal auditory canal and may mimic benign acoustic tumors transiently. When single lesions are seen, the findings are nonspecific; however, when multiple lesions are in the CSF or brain or when multiple cranial nerves are affected and dural enhancement is present, the diagnosis is clear. The prognosis for a patient with carcinomatosis is poor.

The temporal bone is susceptible to any neoplasm that typically metastasizes to bone. Hematogenous spread typically occurs from tumors of the breast, lung, stomach, prostate gland (Fig. 15-51), or kidney. These lesions cause a diffuse or focal osteolytic destructive pattern. There may be postcontrast enhancement, especially if both the epidural space and the bone are involved. Differentiation of glomus tumors from renal carcinoma metastases may be difficult, since both tumors are highly vascular. Prostatic tumors may cause osteoblastic changes that simulate a sclerosing inflammatory process, a meningioma, or Paget's disease.

Traumatic Injuries

The common local serious consequences of temporal bone trauma are hearing loss, CSF fistula, and facial nerve palsy. CT is the best diagnostic modality for identification of fractures.²⁷ Routine head CT examinations of trauma patients should include accurate surveys of the temporal bones. Follow-up detailed, high-resolution images can be acquired if indicated. MRI studies can be of value for vascular and brain injuries.^{48, 59}

Fractures¹

Longitudinal Fractures

Longitudinal fractures (Fig. 15-52) occur along the long axis of the petrous pyramid, which extends parallel to the external and internal auditory canal toward the petrous apex. These fractures typically extend from the temporal squamosa across the roof or posterior wall of the external auditory canal into the tympanic cavity and tegmen tympani. There may be rupture of the tympanic membrane, with hemorrhage in the external auditory canal and middle ear.¹¹

Conductive hearing loss is common and may be caused by ossicular dislocation or fracture or by the presence of intratympanic hemorrhage.⁴⁷ Neurosensory hearing loss is rare with longitudinal fractures but can result from a labyrinthine injury. Facial nerve paralysis occurs in about 20% of instances. Common sites of injury include the geniculate ganglion and the posterior genu.

Axial CT sections favor the visualization of longitudinal

Figure 15–48. Invasive nasopharyngeal carcinoma in a young man with a very aggressive invasive carcinoma of the nasopharynx that has spread into the adjacent skull base, temporal bone, occipital bone, and posterior fossa. *A*, Axial T1-weighted, spin-echo image with fat saturation. A large arching region of tumor infiltration extends from the posterior margin of the nasopharynx all the way back to near the midline occipital bone. *B*, Axial T1-weighted spin-echo image with fat saturation centered more cephalad than in *A*. There is extensive enhancement of Meckel's caves, the right internal auditory canal, and the dural surfaces of the posterior right temporal bone.

Figure 15-49. Perineural spread into geniculate ganglion in a middle-aged woman presenting with a long history of progressive right facial palsy. A CT-directed needle biopsy of the parotid showed carcinoma.

A, Axial CT image through the geniculate ganglion and internal auditory canal portions of the facial nerve canal. There is bulbous expansion of the geniculate ganglion canal. A small soft tissue component protrudes into the epitympanic space just medial to the head of the malleus and the body of the incus.

B, Coronal section through the right temporal bone at the level of the horizontal middle ear segment of the facial nerve, the oval window, and the aditus ad antrum. Note the expansion of the facial nerve that protrudes inferiorly overlying the oval window.

Figure 15-50. Metastatic carcinomatosis in a patient with a known primary tumor and presenting with multiple cranial nerve problems, including hearing loss.

A, Axial T1-weighted, 3D Fourier transform, high-resolution, contrast-enhanced MR image through the left internal auditory canal (IAC). The left IAC, cerebellopontine angle (CPA), and surface of the brain stem all enhance. Multiple other small lesions overlie the surface of the cerebellum. Meckel's caves are involved as well.

B, Axial T1-weighted, spin-echo MR image shows "miliary" enhancing metastases of the brain in addition to CPA disease. Isolated involvement of the IAC by carcinomatosis may mimic a small acoustic schwannoma, but frequently other lesions are imaged or multiple clinical findings may suggest a more diffuse process.

Figure 15-51. Metastatic prostatic carcinoma in an elderly man with a history of severe headaches, ear pain, and known prostate cancer. A and B, Axial CT scans of the skull base show extensive mixed lytic and blastic metastases involving the clivus and petrous apices. There is moderate destruction of the inferior portions of the petrous bones bilaterally, with patchy opacification of the mastoid air cells.

fractures. However, subtle ossicular disruptions with small bony fragments may be more readily seen on coronal images.

Transverse Fractures

Transverse fractures (Fig. 15-53) cross the temporal bone from a posterior to an anterior direction. This type of injury is less common, occurring in approximately 20% of instances. There may be associated traumatic lesions involving the temporomandibular joint, mandibular condyle, or skull base.

Transverse fractures frequently cause labyrinthine dysfunction, resulting in a totally "dead" ear whenever the fracture traverses the vestibule, semicircular canals, or cochlea. Bony fragments may impinge on the facial nerve

canal. Facial nerve palsy is commonly present and is the usual reason for radiographic investigation. CT scanning can be used to explore the facial nerve canal and to illustrate the precise site of injury.⁵⁸

Complex Fractures

A variety of comminuted fractures (Fig. 15-54) may affect the temporal bone. Other fractures of the skull base are common, since the skull base acts as a ring. Severe trauma may be associated with the presence of CSF otorrhea or rhinorrhea. Patients with persistent otorrhea or rhinorrhea can be investigated with CT scans after injection of intrathecal water-soluble contrast material. The site of leakage through the temporal bone may thus be identified, facilitating surgical repair. Vascular injuries, such as carotid

Figure 15-52. Longitudinal fracture in a young man presenting with right-sided conductive hearing loss following skull trauma. Coronal (A) and axial (B) CT scans of the right temporal bone show a fracture line (arrowheads) extending obliquely from the superior lateral portion of the mastoid air cells into the tympanic cavity. There is patchy air-fluid level opacification of the tympanic cavity and mastoid air cells because of hemorrhage and fluid. The ossicles are not displaced.

Figure 15-53. Transverse fracture. *A*, Axial CT image through the cochlea demonstrates dislocation of the ossicles (head of the malleus) into the external auditory canal and tympanic membrane. The normal position of the long process of the malleus is not seen. A linear fracture crosses obliquely into the jugular fossa. *B*, CT section through the epitympanic space demonstrates an absence of the head of the malleus and the body of the incus; they have been dislocated inferiorly. An oblique transverse fracture runs posterior to the posterior semicircular canal. A fracture of the geniculate ganglion canal is too wide to be normal. The mastoid air cells are partially opacified. A balloon is present in the carotid canal as a result of a carotid-cavernous fistula.

Figure 15-54. Comminuted fracture in a young man who sustained a severe traumatic skull and brain injury. Axial CT image through the right internal auditory canal (iac) shows multiple longitudinal (*black arrowheads*) and transverse (*black arrows* and *white arrowheads*) comminuted fractures. The lateral semicircular canal (*double-headed arrows*) is avulsed, and the malleus (*white arrow*) and incus are dislocated from the epitympanic space. The air spaces are opacified with fluid. Cerebrospinal fluid or otic capsule fistula could not be excluded.

Figure 15-55. Bilateral cochlear otosclerosis in an adult with a history of progressive bilateral neurosensory hearing loss. A and B, Coronal CT scans of the left ear show a rim of hypodensity paralleling the left cochlea (*arrowheads*). This lucency represents an area of the enchondral layer of bone formation. C and D, Axial CT scans of the right ear show similar findings (*arrowheads*). (A–D, Courtesy of Dr. Galdino Valvassori.)

dissection and carotid cavernous fistulas, may also be seen. Both MRI and angiography are of value.

Facial Nerve Injury

Transient facial nerve paralysis may occur after temporal bone injury as a result of edema (see Fig. 15-53). Contusion of the facial nerve occurs at the site of greatest narrowing. Whenever there is persistent dysfunction, surgical exploration of the facial nerve may be indicated.⁶⁰ Preoperative CT examination can identify the site of injury.²⁷

Metabolic and Dysplastic Lesions

The petrous temporal bone may be affected by a variety of primary bone diseases that can involve other portions of the skeleton. When they involve the temporal bone, the significance is related to disturbances of hearing, balance, or facial nerve function. Thus, these afflictions usually require detailed, high-resolution CT evaluation of the temporal bones.

Otosclerosis

Otosclerosis (Fig. 15-55) is more accurately called *otospongiosis*, which reflects the active phase of the disease.

Figure 15-56 Prostheses. *A*, Axial CT section through the round window and cochlea demonstrates a cochlear implant. The wire enters the round window and the basal turn of the cochlea and is seen as a thin, linear density. *B*, Coronal CT scan shows a metallic prosthetic stapes angled from the long process of the incus up into the oval window niche. It ends at the stapes footplate in a normal position.

Illustration continued on following page

Figure 15-56 Continued C, Coronal CT scan shows a small tympanostomy tube as two thin linear densities protruding from the tympanic membrane. The middle ear and the external auditory canal are clear. Other structures depicted include the cochlea and the geniculate ganglion.

This primary bone disease is fairly common; histological studies show that it occurs in up to 10% of the population, but clinical symptoms are present in only 10% of those with histologic changes. If the disease process involves the labyrinthine capsule, there may be progressive neurosensory hearing loss. Involvement of the oval window and stapes footplate causes conductive hearing loss, whereas involvement of the cochlea causes neurosensory hearing loss. Occasionally, there is a combination of both types of deafness.

The human otic capsule is unique because mature bone remains in a state of primary ossification. This enchondral capsule is never replaced by mature haversian osseous tissue. Pathologically, otosclerosis consists of replacement of the primitive and chondral bony capsule by mature haversian bone. The disease begins as scattered foci of bony resorption containing many osteoclasts, osteoblasts, and irregular, loose trabeculae. These so-called spongiotic foci are less dense than normal bone and represent the *active* disease (otospongiosis), which can cause hearing loss. In the *inactive* (*sclerotic*) phase, a few cells or vessels are contained within sclerotic foci. Otosclerosis usually begins before puberty, is familial, and is bilateral in about 90% of patients. Women are affected twice as often as men.

Cochlear (labyrinthine) otosclerosis (see Fig. 15-55) has a characteristic CT appearance. Crescentic low-density regions parallel the margins of the basal turn of the cochlea, the entire cochlea, or the whole otic capsule. On CT scans, the active or spongiotic phase appears as areas of demineralization involving the enchondral layer of the cochlea or the otic capsule.³⁷ CT scanning may be able to show a fine enchondral band of decreased density in some patients with normal hearing. Presumably, this represents histologic (incipient) otosclerosis. Other patients may have areas of inactive otosclerotic foci.

Spongiotic changes involving the oval window and stapes footplate are referred to as *fenestral otosclerosis*, a type that is more difficult to identify on CT scans. However, the otosclerotic phase may be readily appreciated.³⁶ Patients with early stapedial vestibular otosclerosis show small lucencies within the otic capsule with soft tissue swelling predominantly at the anterior margin of the oval window. Later on, dense otosclerotic foci may cover these structures. The round window may also be affected.

Most patients with otosclerosis are treated with stapedectomy and prosthetic implants. State-of-the-art CT scanning may be used in evaluating metallic, plastic, and ceramic prostheses after such procedures (Fig. 15-56).¹³ Patients who experience recurring hearing loss after ossiculoplasties may also be examined by CT to determine whether dislocation of the prosthesis has occurred.

Osteogenesis Imperfecta

Osteogenesis imperfecta (Fig. 15-57) produces otic capsule and oval window changes identical to those seen with otosclerosis.^{36, 37} Deafness is a common finding, with progressive hearing loss starting in childhood or as late as the third decade of life. When the otosclerotic process extends into the medial aspect of the cochlear capsule, the enchondral band of demineralization produces a characteristic double lucency appearance (*double-ring sign*) of the cochlea. If the process is severe and extensive, the outline of the cochlea becomes totally indistinguishable from the surrounding petrous bone.

Paget's Disease (Osteitis Deformans)

Paget's disease (osteitis deformans) (Fig. 15-58) is a chronic inflammatory disorder that results in the eventual

Figure 15-57. Osteogenesis imperfecta in a young patient with hearing loss and facial palsy. *A*, Coronal CT image demonstrates a broad lucency adjacent to the basal turn of the cochlea. There is also thickening of the soft tissues filling the oval window niche, mimicking severe fenestral and cochlear otosclerosis. *B*, Coronal image, anterior in relationship to *A*, shows erosive changes involving the geniculate ganglion region and paralleling the cochlea.

replacement of normal bone by thickened, less dense, weaker bone. The incidence of Paget's disease in patients over 40 years of age is 3%, and the skull is affected in 65% to 70% of patients. When Paget's disease involves the temporal bone, it is most often bilateral, with similar structural changes in a given pair of temporal bones.

Paget's disease can produce narrowing and tortuosity of the external auditory canal. Exostoses and chronic external otitis are fairly common and lead to the secondary development of external canal cholesteatomas. In addition to the

overgrowth of bone in the external auditory canal (which may cause conductive hearing loss), there may be concentric overgrowth of the tympanic bone. This bony overgrowth leads to conductive hearing loss because the tympanic annulus and tympanic membrane become relaxed, resulting in inadequate function.

Paget's disease can affect the inner ear, with demineralization of the petrous pyramids and labyrinthine capsule. These areas of demineralization are intermixed with areas of apparent thickening in the skull base.

Figure 15-58. Paget's disease in an older man with bilateral neurosensory hearing loss. Axial CT scan of the left ear shows tremendous thickening of the entire temporal bone. The central portion of the otic capsule adjacent to the vestibule and semicircular canals are least affected. The internal auditory canal is not visible because of pagetoid changes in the inner ear. (Courtesy of Dr. Jacqueline Vignaud.)

Fibrous Dysplasia⁴³

Fibrous dysplasia (Fig. 15-59) is a disease manifested by aberrant maturation of bone. Histologically, normal spongiotic bone is replaced and the medullary cavities of affected bones are filled by abnormal fibrous tissue. The bony structures have an increased density, in comparison with normal bone and in contrast to Paget's disease, where the thickened bone is less dense than normal bone. Solitary monostotic fibrous dysplasia of the petrous pyramid may

occur, but widespread involvement is more common. The changes in the temporal bone are usually proliferative, whereas the changes in the calvaria are usually expansile.

Patients with fibrous dysplasia can show both conductive and neurosensory hearing loss. Conductive hearing loss results from narrowing or occlusion of the external auditory canal. Such stenosis is common and may be responsible for cholesteatoma formation.²³ These external canal cholesteatomas may lead to a condition of external canal stenosis termed *keratosis obturans*. The mastoid portion may show hyperostotic thickening of cell walls, leading to obliteration of mastoid air cells.

Fibrous dysplasia may involve the petrous portion of the temporal bone. Areas of sclerosis may alternate with areas of resorption and expansion. The thickened bone is regular and typically is not fragmented.²⁷ Frank destruction of the petrous ridge or otic capsule is usually associated with malignant degeneration, which occurs in approximately 1 in 200 patients.

Osteopetrosis

Osteopetrosis is a heredity disorder characterized by excessive calcification of bones and spontaneous fractures. The disease process may be mild, with a benign course and normal life span (autosomal dominant). Alternatively, the disease may follow a malignant course, causing death early in life (autosomal recessive). Patients can have hydrocephalus, subarachnoid hemorrhage, extramedullary hematopoiesis, and severe headaches with progressive visual and hearing loss.

CT scans show extensive sclerosis of the petrous pyramids. There is a normal density difference between the otic capsule and the surrounding bone. Progressive neurosensory hearing loss is caused by obliteration of the labyrinth or narrowing of the internal auditory canals.

Figure 15-59. Fibrous dysplasia in a young man with a long-standing, left-sided conductive hearing loss and stenosis of the left external auditory canal (EAC). A and B, Axial CT scans of the left temporal bone show tremendous bony overgrowth, with diffuse sclerosis and thickening of the temporal bone. The labyrinthine capsule is still identifiable despite excessive new bone formation. Note the total obliteration of the mastoid air cells. The tympanic cavity is compressed, and the EAC is severely narrowed. A soft tissue mass (arrow) in the EAC represents a secondary cholesteatoma (*keratosis obturans*) caused by chronic obstruction.

Acknowledgments

We would like to acknowledge Linda Chakeres for editing the complete text and John Croyle for printing most of the images. We would also like to thank Anton Hasso, M.D., C. Roger Bird, Barbara Carter, Charles Lanzieri, Theodore Larson, William Lo, Galdino Valvassori, Jacqueline Vignaud and Jeffrey Jones, M.D., for the use of their figures.

The Sinonasal Cavity

Charles F. Lanzieri

Embryology²⁵

The nasal sac or primitive nasal cavity begins to develop from the stomodeum as early as the 24th fetal day. The stomodeum forms on the ventral and superior aspect of the embryo between the first branchial arches. There is an eventual thinning of the cellular layers to first form a buccopharyngeal membrane. At about the 28th fetal day, the buccopharyngeal membrane disappears, and communication between the amnion and internal cavity is established.

At about the 28th fetal day, the nasal placode first forms just superior to the first branchial arch and just lateral to the stomodeum. At about the 31st day, there is an infolding in the center of the nasal placode, which forms the nasal pit. The nasal sacs grow dorsally from each nasal pit into the ventral portion of the developing brain. At first, the sacs are separated from the oral cavity by the oronasal membrane, but this membrane soon ruptures, bringing the nasal and oral cavities into communication. These regions of continuity are called the *primitive choanae*, which lie posterior to the primary palate. After the secondary palate develops, the choanae are located at the junction of the nasal cavity and the pharynx.

At about the 48th fetal day, the lateral palatine processes fuse with each other and the nasal septum; the oral and nasal cavities are again separated. This fusion also results in separation of the nasal cavities from each other.

While these changes are occurring, the superior, middle, and inferior conchae develop as elevations on the lateral wall of each nasal cavity; in addition, the ectodermal epithelium in the roof of each nasal cavity becomes specialized into the olfactory region. Some cells differentiate into olfactory cells that give origin to fibers that grow into the olfactory bulbs of the brain.

The paranasal sinuses develop during late fetal life and early infancy as small diverticula of the lateral nasal wall. During childhood, these sinuses extend into the maxilla, the ethmoid, and the frontal and sphenoid bones, reaching their maximum size at puberty.

Anatomy and Normal Variants

The nose serves to inspire and expire air and to warm, moisturize, and filter that air. It has been estimated that approximately 2 L of water is produced daily by the serous glands of the sinonasal cavity and is used to humidify the inspired air.³⁰ A surface film of mucus also traps larger particles, and the action of the associated cilia serves to transport the mucus and particulate matter posteriorly and inferiorly into the nasopharynx at approximately 1 cm/minute.³⁰

The nasal mucosa is vascular pseudostratified columnar ciliated epithelium that contains both serous and mucous glands.¹¹ In the most superior portion of the nasal fossa is a less vascular and nonciliated epithelium, the olfactory mucosa.¹¹ It contains the efferent axon of the bipolar olfactory nerve fibers that transform the physical stimuli of odors into nerve impulses that are then transmitted through the cribriform plate into the olfactory gyri.¹¹ A special lipolipid is secreted by this mucosa, which is necessary for the dissolution of odors that are transmitted to the bipolar neurons.⁵¹ Since smells can be perceived only if the substance is in solution, a dried olfactory mucosa has no perception of smell.¹⁸ In addition, there is no ciliary action within the olfactory mucosa, so that sniffing is necessary to bring the fragrance-bearing material to the olfactory recess and to this mucosa.⁴⁵

The medial wall of each nasal cavity is the nasal septum, which is partially bony and made up of the perpendicular plate of the ethmoid and the vomer; the more anteroinferior portion of the nasal septum is cartilaginous. The lateral wall of the nasal fossa, however, is extremely complex.^{2-6, 11, 18, 30, 45, 51} The ostia for the paranasal sinuses open into the lateral wall, which is separated into either three or four fossae or meatus by either three or four nasal turbinates or conchae (Fig. 16-1).

The turbinates are delicate projections of bone that become smaller as they ascend superiorly into the nasal cavity. Because the paranasal sinuses develop predictably from outpouchings of the lateral nasal wall, the drainage pattern is also predictable. The frontal and anterior ethmoid

Figure 16-1. Anatomic drawing. The medial aspect of the right nasal cavity is shown. The superior, middle, and inferior turbinates divide each nasal cavity into three fossae or meatus. This anatomy and the anatomic variations are important for understanding disease processes and for surgical planning.

and maxillary sinuses nearly always drain between the middle and inferior nasal turbinates into the middle meatus. The posterior ethmoids nearly always drain between the superior and middle turbinates or middle meatus. The sphenoid sinus may drain between the superior and supreme turbinate or superior meatus or directly into the most superior and posterior recess of the nasal cavity (the *sphenoethmoidal recess*). Functionally, it is useful to think of each of these groupings of sinuses and their respective meatus as a single unit. Clinically, the most important of these is the middle meatus, also called the *ostiomeatal unit*. In the common inflammatory syndromes, the middle meatus and associated anterior ethmoid, frontal, and ipsilateral maxillary sinuses are most often involved as a unit.

The inferior turbinate is covered by a thick mucous membrane that contains a dense venous plexus with large vascular spaces and erectile tissue. In this sense, it is somewhat different from the other turbinates. The nasolacrimal duct is the only consistent opening within the inferior meatus. If one were to remove the middle turbinate and examine the middle meatus, one would find a slightly curved slit, the hiatus semilunaris, on the lateral surface of the middle meatus. Into this slit drain the ethmoid air cells and maxillary sinus. Into the anterior recess of this slit drains the frontonasal duct if this duct exists.

In approximately 50% of patients, the nasofrontal duct drains directly into the ethmoid air cells, which then drain into the frontal recess. This important drainage space is covered medially by the uncinate process of the ethmoid bone. The length and configuration of the uncinate process determine the ease of upward transportation of mucous secretions.

Just superior to the hiatus semilunaris lies the bullosa ethmoidalis, which is an inferiorly placed ethmoid air cell. The size and degree of pneumatization of this ethmoid bulla determine the size of the opening of the ostiomeatal unit into the middle meatus. The relative sizes, shapes, and configurations of these structures determine, to some ex-

tent, the frequency of obstruction and the propensity for inflammatory changes within the ostiomeatal unit.

In approximately 80% of the population, there is an alternating pattern of increased production of secretions and shunting of blood into the vascular mucosa of the inferior and middle turbinates, from side to side.⁵² The nonfunctioning side retains secretions and becomes vascularly congested and engorged, while the passage of respiratory air is carried almost entirely by the open nasal side. The frequency of the cycle varies from 30 minutes to several hours. It is important to remember the existence of the nasal cycle in a fairly large portion of the human population when interpreting studies of the paranasal sinuses, because normally engorged turbinates may be mistaken for inflammatory or neoplastic processes.

The vascular and lymphatic anatomy of the nasal fossa is highly complex.²⁹ The arterial supply involves both branches of the internal and external carotid arteries. Of the many arteries that may supply portions of the sinonasal cavity, the sphenopalatine division of the internal maxillary artery is the most important (Fig. 16-2). This artery arises from the sphenopalatine portion of the internal maxillary artery and exits the pterygopalatine fossa. It then enters the nasal fossa posterior and superior to the middle turbinate.

The sphenopalatine artery has two major divisions: a posterolateral nasal branch and a posterior septal branch. The lateral nasal arteries ramify over the turbinates before providing collateral circulations to the paranasal sinuses. The trunk of the sphenopalatine artery extends medially along the roof of the nasal cavity, giving the posterior septal arteries as their terminal branches.

The termination of the posterior septal arteries at the anterior nasal septum continues as the nasopalatine artery, which exits the incisive canal and anastomoses with the greater palatine artery. Lymphatic drainage from the anterior portion of the sinonasal cavity is anteriorly into the face and finally into the submandibular group of lymph nodes. From the posterior half of the sinonasal cavity and

Figure 16-2. Vascular anatomy. **A**, Selective injection into the external carotid artery. The main supply to the nasal cavity and sinuses from the external carotid is via the sphenopalatine artery (short arrow). The terminal branches include the descending palatine artery (arrowhead), the inferior orbital artery (curved arrow), and the septal arteries (small arrows). The middle meningeal artery (triple arrows) is also shown. This vessel may be important for supply to the sinuses and orbits. **B**, Selective injection into the ophthalmic artery (curved arrow). The retinal blush (large arrow) is supplied by the central retinal artery (small arrow). Proximal to the origin of the central retinal artery, other branches from the ophthalmic artery may supply the soft tissue including the extraocular muscles (mid-sized arrow). The anterior and posterior ethmoidal arteries, which are too small to be seen in the normal patient, also arise from the ophthalmic artery.

Figure 16-3. Supraorbital ethmoid. Within the right frontal sinus in this coronal CT scan is an isolated air cell (arrow) whose drainage pathway could be shown to be into the superior meatus. This air cell is therefore a posterior ethmoid air cell and is located within the right frontal sinus, which is important in understanding disease processes and surgical planning.

nasopharynx, lymphatic drainage is into the retropharyngeal and internal jugular lymph node chains.⁴⁵

The venous drainage of the sinonasal cavity is into the anterior facial vein, which then anastomoses with the common facial vein and drains blood into the internal jugular vein. The anterior facial vein also anastomoses with the ophthalmic veins, which drain directly via the pterygoid venous plexus into the cavernous sinus. Therefore, infection within the sinonasal cavity may gain rapid access to the cavernous sinuses and cranial cavity.³⁰

Supply from the internal carotid artery via the ophthalmic artery is through the anterior and posterior ethmoidal arteries, which send numerous small branches through the cribriform plate to anastomose with the nasal branch of the sphenopalatine artery (Fig. 16-3). An important anastomotic region is Little's or Kiesselbach's area, located anteriorly and inferiorly on the nasal septum.²⁹ This region is supplied by multiple branches of the facial, sphenopalatine, and greater palatine arteries and is often referred to as *Kiesselbach's plexus*. This is the site of the majority of epistaxis episodes.

Anatomic Variations

Frontal Sinuses

Embryologically, the frontal sinuses are anterior ethmoid air cells that grow into the frontal bone. They drain via the nasofrontal duct into the anterior portion of the infundibulum. The frontal sinuses are absent at birth and begin to develop after the second year of life.⁸ In approximately 5% of the population, they are absent. The upward growth of the paranasal sinuses carries them to the midportion of the orbit at approximately age 4 years and to the top of the orbits at about age 8 years.²² At approximately 10 to 12 years of age, the final adult size is reached.⁴⁹

The size of the frontal sinuses depends on mechanical stresses from mastication and the effect of growth hormone. The intrasinus septum lies in the midline at the level of the inferior extent of the frontal sinuses but may extend far to one side, depending on the different growth rates of the two frontal sinuses.

Ethmoid Complex

The ethmoid sinuses begin to develop in the 5th month of fetal life.⁸ There is wide variation in the numbers and sizes of cells. The anterior ethmoid air cells are more numerous, with more numerous septa than in the posterior ethmoid air cells. Pneumatization of the ethmoids is widely variable. Far anterior ethmoid air cells (aggrer nasi) cells are represented in a large portion of the population and may be situated anterior to the frontonasal duct.⁴⁵ During endoscopic nasal sinus surgery, the swelling of the aggrer nasi may be mistaken for the nasolacrimal duct.^{16,48} The anterior ethmoid air cells may also extend superiorly into one of the frontal sinuses and into the roof of the orbit where they mimic the frontal sinus. These supraorbital ethmoid air cells should be considered distinct from the frontal sinuses themselves (see Fig. 16-3). The inferiorly located posterior ethmoid air cells may extend laterally in the infraorbital direction and bulge into the maxillary sinuses. This is the second type of "sinus within a sinus" (Fig. 16-4). The ethmoid air cells may pneumatize the middle turbinate; this condition is known as *concha bullosa* and occurs in approximately 10% of the population.^{45,48} In rare instances, the superior turbinate or uncinate process may be similarly pneumatized. The concha bullosa may contribute to obstruction and inflammatory changes within the ostiomeatal unit (Fig. 16-5).

Figure 16-4. Infraorbital ethmoid. The right-sided maxillary sinus appears to have a horizontal septation within it. Closer inspection reveals that the superior portion of the right-sided maxillary sinus is actually a posterior ethmoid air cell (large arrow) and drains its contents superior to the middle turbinate (small arrow). This structure therefore represents an ectopic posterior ethmoid air cell within the expected position of the right-sided maxillary sinus, which can also be seen (angled arrow).

Figure 16-5. Concha bullosa. Pneumatization of the middle turbinate by anterior ethmoid air cells may cause this structure to enlarge. On this coronal CT scan, one can appreciate bilateral pneumatization of the middle turbinates, larger on the right (arrow). The redundant mucosa on the surface of the right middle turbinate further narrows the middle meatus on the right side and may be the source of obstruction and secondary infection.

Sphenoid Sinus

The sphenoid sinuses begin to develop in the 4th or 5th fetal month from a posterior outgrowth of the nasal capsule into the sphenoid bone. The sinus undergoes its major development beginning in about the 3rd year of life and reaches its adult size early in the 2nd decade of life.⁴⁹ In most people, the sphenoid sinus extends posterior to the anterior sella wall and beneath the sella floor. In less than half of the population, they extend only to the anterior wall of the sella turcica.²⁰

In a small but important group of individuals (<1%), the sphenoid sinus does not reach the anterior wall of the sella turcica. This is important to the neurosurgeon considering a transsphenoidal hypophysectomy. The sphenoid sinus may extend laterally and inferiorly into the pterygoid plates of the sphenoid bone as well as superiorly and laterally into the posterior and anterior clinoid processes. The pterygoid process is described as being extensively pneumatized in nearly 10% of the population. The number of sphenoid air cells ranges from 1 to 3 with approximately one third of the population in each of these categories.

Maxillary Sinus

The maxillary sinus is the first sinus to form, beginning in approximately the 17th day of gestation. By the end of the first year of life, the lateral extent of the maxillary sinus extends into the medial portion of the floor of the orbit and reaches the infraorbital canal by the 2nd year. The adult configuration usually is attained early in the second decade of life.²⁴ Hypoplasia of the maxillary sinus occurs in between 1% and 7% of the population and may result from trauma, infection, surgical intervention, or irradiation. There are congenital first and second branchial

Figure 16-6. Maxillary hiatus. Coronal CT scan from a 9-year-old boy. The maxillary sinuses begin as lateral outpouchings from the lateral nasal wall and are usually present at birth, although they may not be fully pneumatized. There is progressive enlargement of the maxillary antrum in all directions. In the coronal plane, the lateral margin of the maxillary sinus usually reaches the level of the groove for the infraorbital nerve (small arrow) at about age 8 years. This patient has acute sinusitis with air-fluid levels present in both maxillary sinuses. Although the natural ostia of both maxillary sinuses are obstructed by a soft tissue mass, there is a small accessory opening for the left maxillary sinus called the maxillary hiatus (curved arrow), which may help to drain the left maxillary sinus secretions.

arch anomalies such as Treacher Collins syndrome, in which there is congenital hypoplasia of one of the maxillary sinuses.

The maxillary sinus is unique for its relationship to the upper molar teeth and canine teeth, which may project into the maxillary antrum. Inflammatory, neoplastic, and congenital odontogenic processes uniquely affect the maxillary sinuses. In the medial wall of the maxillary sinus is a bony dehiscence known as the *maxillary hiatus* (Fig. 16-6). This is separated from the nasal cavity by the mucous membranes of both the nasal cavity and the maxillary sinus. This membranous septum is important to the surgeon seeking to irrigate the antrum and to establish a secondary pathway of drainage. It is also important for the radiologist to recognize, because it may appear to be a direct communication between the nasal cavity and maxillary sinus on imaging examinations.

Imaging Technique

Computed Tomography

Computed tomography (CT) of the paranasal sinuses is usually requested when inflammatory or neoplastic processes of the paranasal sinuses are suspected and when suspected inflammatory disease does not respond to conservative therapy.¹ An initial screening examination has been proposed as a substitute for plain film examination (Fig. 16-7).

Several types of protocols are used for this purpose. A

particularly effective protocol has been a limited number of axial sections through the paranasal sinuses. Approximately five or six axial images, beginning at the alveolar ridge and extending through the top of the frontal sinus, can effectively produce two images through each sinus in the axial plane in approximately 15 minutes of room time and 1 or 2 minutes of scan time. This technique has the advantage over plain film radiography in its ease of performance for both patient and technologist. It is also highly reproducible compared with plain film examinations. There is a low repeat rate of images, and the radiation dose is significantly less than the standard for plain films of the paranasal sinuses. This limited examination can be used to establish the presence of inflammatory disease on a noncontrast CT scan and for follow-up examination during medical therapy.

If surgical intervention is contemplated, especially if endoscopic nasosinus surgery is proposed, a more detailed view of the anatomy within the sinonasal cavity is re-

quired.⁵⁴ For this purpose, overlapping thin sections through the paranasal sinuses are most useful (Fig. 16–8).

The ideal examination plane is perpendicular to the hard palate; however, the nearly ubiquitous presence of dental amalgam often forces the use of a prodental or retrodental plane. This study is almost always performed without the use of intravenous (IV) contrast injection. Contrast enhancement of paranasal sinus masses has not been shown to aid in the differential diagnosis; rather, the bony architecture and anatomic configuration as well as the anatomic variations are the most important information sought in this examination.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) studies currently offer some advantages over CT scans in imaging of the paranasal sinuses. The main purpose of the MRI study is

Figure 16–8. Normal coronal anatomy. *A*, The nasal fossa can be divided into three separate meatus based on the relationship of spaces within the nasal cavity to the turbinates. The nasal lacrimal duct drains into the inferior meatus below the inferior turbinate. *B*, The frontal sinuses, anterior ethmoid air cells (*long arrow*), and maxillary sinus drain into the middle meatus. The uncinate process of the ethmoid bone (*curved arrow*) is a membranous or ossified structure that forms the medial border of the infundibulum of the maxillary sinus. The posterior ethmoid air cells (*short arrow*) and sphenoid sinus drain into the superior meatus, inferior to the superior turbinate. *C*, A common anatomic variation of the middle turbinate, which on the left side curves in the lateral rather than the medial direction (*arrow*). Like the concha bullosa, this narrows the middle meatus and may lead to obstruction and inflammatory change within the ostiomeatal unit. Note the air-fluid level in the left maxillary sinus.

Figure 16-9. Normal MRI study. This T1-weighted image (TR500, TE32) was obtained in the coronal plane following contrast injection. The vascular nature of the turbinates is manifested as intense enhancement following contrast injection. The turbinates and nasal mucosa alternately engorge with blood and then shrink. This patient may be in the left-sided engorgement phase of the nasal cycle. Note the enlarged turbinates and thickened nasal mucosa.

to map the extent of a sinonasal mass or inflammatory process into either the orbit or cranial cavity. For this purpose, the multiplanar capabilities of MRI are unsurpassed. In addition, the signal characteristics of a sinonasal mass may help to distinguish inflammatory from neoplastic sinonasal diseases.^{40, 41, 44} If the mass is neoplastic, this ability allows for better surgical planning and radiation planning.

The use of gadolinium has been proposed as a method for differentiating sinonasal neoplasms from inflammatory masses.¹⁷ The MRI protocol for examination of the paranasal sinuses should include T1- and T2-weighted images in two planes, *axial* and *coronal*. Sagittal or off-sagittal images parallel to the optic nerve may then be obtained if necessary. Gadolinium (Gd-DTPA) may then be given, and repeated scanning can be performed according to the preference of the radiologist (Fig. 16-9).

Inflammatory Processes

The “common cold” is a viral rhinitis thought to be secondary to rhinoviruses, parainfluenza, and influenza viruses.³³ Clinically, these infections last for 1 to 3 days, and the anatomic changes within the paranasal sinuses are completely reversible. There is usually mucosal thickening within the nasal fossa and turbinates as well as the mucosa of the paranasal sinuses. If a sinus ostium is obstructed, an acute bacterial sinusitis may result in superinfection. The most common bacterial pathogens in these cases are streptococci, *Haemophilus*, and staphylococci as well as *Pseudomonas*. Anaerobic infections may also occur secondary to *Bacteroides*.¹⁰

As previously noted, because of the unique anatomy of the maxillary sinus, the presence of the roots of the molar

teeth, infections secondary to odontogenic causes account for approximately 15% of maxillary sinus infections.⁴⁵ The imaging hallmark of acute bacterial sinusitis is an air-fluid level within the affected sinus (see Fig. 16-6). This is most commonly visualized within the maxillary sinus. Repeated episodes of acute and subacute sinusitis may result in a persistent change within the paranasal sinuses (chronic sinusitis). The intrasinus mucosa may then be atrophic or hypertrophic. In any event, there is loss of the normal ciliary function and flow of secretions, resulting in a sinus that is less resistant to infection.⁴⁵ Thus, a vicious circle of infection and reinfection occurs.

Although allergic sinusitis and viral sinusitis tend to be symmetrical and involve the nasal fossa as well as the paranasal sinuses, bacterial sinusitis tends to be isolated to a single sinus or a group of contiguous sinuses. Additionally, the presence of nasal polyps is most common in allergic, rather than infected, patients (Fig. 16-10).

In the pediatric population, sinus opacification and mucosal thickening should be reported, but their significance remains in doubt especially in children under the age of 2 years.⁴⁷ Tears, normal retained secretions, and normal redundant mucosa may account for apparently abnormal findings in this population (see Fig. 16-9).

Air-fluid levels within the maxillary sinuses are usually the result of acute bacterial sinusitis. Although it has become a much less common procedure in recent years, lavage of the maxillary antrum with saline solution was previously a common cause of an air-fluid level within the maxillary sinus as well. In instances of direct trauma or barotrauma in individuals exposed to high altitude or deep immersion, hemorrhage within one of the paranasal sinuses may mimic acute sinusitis. Hemorrhage may also mimic acute sinusitis in patients with bleeding disorders such as hemophilia, or in cases of epistaxis. Intubated patients (specifically those with nasotracheal intubation) may present with air-fluid levels, especially within the sphenoid sinuses from mechanical changes within the nasopharynx. These are not necessarily acute bacterial infections (Box 16-1).

Ostiomeatal Unit

Recent advances in the understanding of mucociliary function and the pathophysiology of the nasal cavity and paranasal sinuses, along with the concomitant advances in functional endoscopic surgery directed toward restoring normal mucociliary drainage and ventilation of the sinuses, have required a more detailed evaluation of the functional anatomy of the paranasal sinuses in preoperative patients.^{14, 54} The ostiomeatal unit is the middle meatus of the nasal cavity and the sinuses which that meatus serves to drain: These are the frontal sinus, the anterior ethmoid sinuses, and the maxillary sinus. Radiographic evaluation is therefore directed toward assessing the patency of the maxillary sinus ostium, the ostia of the anterior ethmoid air cells, the hiatus semilunaris, and the middle meatus.

The coronal plane is best for demonstrating the anatomy of the ostiomeatal unit.²¹ One should attempt to identify the natural ostium of the maxillary sinus and anterior ethmoid sinuses, establish their patency, and ascertain that

Figure 16-10. Nasal polyps. Retention cysts and nasal polyps are indistinguishable on CT scans and MRI studies. Rounded, soft tissue density structures within the maxillary sinuses on the CT scan (A) represent retention cysts or polyps when there is no bone destruction or expansion. These are usually asymptomatic; however, when they occur near the orifices of sinuses such as in the infundibulum (arrow), postobstructive changes in the corresponding ostiomeatal unit may occur. On MRI examination following contrast injection (B), there is linear enhancement on the surface of most polyps and retention cysts. This helps to distinguish them from solid masses.

these spaces are free of mucosal thickening or polypoid masses. In addition, various anatomic variations may predispose to poor mucociliary function.^{14, 48, 54} The most common of these is concha bullosa, which is an enlarged and pneumatized middle turbinate. This is most often small and without impairment of the function of the middle meatus, but it may become large and compress the uncinate process, obstructing the middle meatus and infundibulum. The middle turbinate may also be curved so that its convexity is directed toward the medial wall of the nasal septum. The concave portion of the middle turbinate then serves to narrow the middle meatus. This anatomic variation is known as a *paradoxical middle turbinate*.

There are several variations involving the anterior ethmoid air cells, which may narrow the middle meatus. Ethmoid air cells that extend inferior to the ethmoid bulla and within the roof of the maxillary sinus may narrow the infundibulum from above. These are called *Halle cells*. The anterior ethmoids, which form the superior contour of the middle meatus, are called the *ethmoid bullae*. These may become enlarged and extend into the hiatus semilunaris, blocking the infundibulum. The uncinate process itself may be of varying sizes, shapes, and positions.¹⁶ For example, if it is elongated and directed laterally, obstruction of the infundibulum may result. The nasal septum is deviated to one side or another in more than 90% of people. When the deviation is significant or when a small bone spur forms at the cartilaginous junction with the bony portion of the septum, obstruction of the middle meatus may also result.

Box 16-1. Unilateral Sinus Opacification

serous retention cyst, or a polyp. These three entities cannot be clearly differentiated from one another on sectional or plain film imaging modalities. This is of little consequence since all three are regarded as common benign entities (Box 16-2).

Fungal Diseases

Various fungal diseases involve the sinonasal cavities. The most common and most important of these include mucormycosis, histoplasmosis, and candidiasis and dis-

Figure 16-12. Cavernous sinus involvement. Cavernous sinus thrombosis or thrombophlebitis is most often secondary to sinus infection. Note the opacification in this patient's posterior ethmoid and sphenoid sinus on the left side. There is secondary enlargement and enhancement of the left cavernous sinus (arrow) and optic nerve.

eases caused by *Aspergillus*.²⁷ The radiographic features of fungal diseases involving the paranasal sinuses are usually nonspecific and include opacification of the sinus as well as a sclerotic bony reaction (Fig. 16-11). Air-fluid levels are uncommon and, when present, suggest a bacterial infection rather than a fungal infection.⁴⁵

Mucormycosis occurs almost exclusively in immunocompromised hosts. Fifty percent to 75% of these patients have poorly controlled or uncontrolled diabetes mellitus. The causative organisms are invasive and tend to spread rapidly from the nasal cavity to the paranasal sinuses.²⁷ They have a propensity for invading blood vessels. In doing so, they denude the endothelial lining and initiate thrombosis, which leads to venous cerebral infarcts. Invasion of the orbits, cavernous sinuses, and ophthalmic veins is common (Fig. 16-12). Intracranial extension, via emissary vein, may extend to the meninges and eventually lead to cerebral abscess (Fig. 16-13). Progression may be rapid, occurring within a few days. The disease also occurs in immunocompromised patients with hematologic malignancies and those with acquired immunodeficiency syndrome (AIDS). Because fungi tend to bind calcium, manganese, and other heavy metals, a large number of affected paranasal sinuses may appear hyperdense on CT scans and of low signal intensity on MRI studies⁵³ (Box 16-3). In the latter stages of infection, bony destruction may mimic an aggressive tumor such as squamous cell carcinoma (Box 16-4).

Figure 16-13. Sinusitis with intracranial extension. These contrast-enhanced T1-weighted images were obtained through the head of a patient with sinusitis and neurologic findings. A and B demonstrate meningeal enhancement (small arrows) in the left frontal region just posterior to the infected left frontal sinus (large arrow). C and D, Adjacent slices reveal the presence of an associated cerebral abscess (arrows) in the left frontal lobe. Cerebral abscess has occurred by direct extension, without apparent bone involvement, probably via emissary veins.

On the other hand, *Aspergillus* infection usually occurs in otherwise healthy patients and has no relationship to pulmonary aspergillosis, which is known to occur in debilitated patients. The radiographic appearance, however, is similar to other fungal infections with opacification of a single paranasal sinus, a hyperdense paranasal sinus on CT scans, hypointense signal on T2-weighted MRI studies from heavy metal, and osseous destruction mimicking aggressive tumor in the later stages. Although less aggressive

than mucormycosis, *Aspergillus* infection may cause a vasculitis that results in cerebral thrombosis as well.

Granulomatous Diseases

Various granulomas produce diseases that may involve the sinonasal cavities. These include granulomas caused by organisms such as *Nocardia* and infectious diseases such as

aspergillosis,²³ actinomycoses,³⁴ tuberculosis, and syphilis.⁵ Granulomas can be caused by autoimmune or collagen-vascular diseases such as Wegener's granulomatosis,³¹ lymphoma or lymphatoid diseases such as midline granuloma, and processes such as sarcoidosis. In addition, granulomas may be the result of exposure to irritants such as beryllium and chromium.

In general, granulomatous diseases affect the paranasal sinuses first by causing a nonspecific inflammatory type of reaction with mucosal thickening and increased secretions.⁴⁵ The nasal septum may exhibit focal thickening, or septal erosions may be found. The paranasal sinuses are usually involved secondary to nasal cavity involvement. The maxillary and ethmoid sinuses, as with inflammatory diseases, are most often affected. When the sinuses are involved, a nonspecific inflammatory reaction is seen. Air-fluid levels are usually not present. Bony changes of the nasal cavity and paranasal sinuses may include thickened and sclerotic walls and septa. This is from the chronic inflammatory reaction (Fig. 16-14).

Wegener's granulomatosis is fundamentally a necrotizing granulomatous vasculitis that initially involves the respiratory tract and eventually spreads to include the kidneys as well as other organs. When the sinonasal cavity is involved, the nasal septum is affected initially with diffuse thickening followed by septal perforation. A more aggressive and idiopathic granulomatous process is so-called idiopathic midline granuloma,¹³ which is characterized by a necrotizing inflammatory reaction involving the sinonasal cavities and midline of the face as well as the upper respiratory tract. This is a more localized disease with the lungs and kidneys unaffected.

Tuberculosis may involve the paranasal sinuses secondary to pulmonary infection. The sinus disease is again nonspecific. Another granulomatous disease involving the paranasal sinuses is actinomycosis, which only rarely involves the paranasal sinuses and is usually the result of direct extension from the mandible.

Figure 16-14. Wegener's granulomatosis. Granulomatous disease within the paranasal sinuses may be manifested as linear enhancement (arrow) or nodule enhancement. Destruction of osseous structures out of proportion to soft tissue thickening should lead one to think of a granulomatous process or lymphoma.

Mucocele

Mucoceleles are the most common expansile lesions of the paranasal sinuses.⁴⁵ A mucocele develops from obstruction of a sinus ostium.⁵⁰ The continued secretions of the sinus mucosa cause expansion and remodeling of the bony margins. Expansion of the sinus cavity causes erosion of internal septa and displacement of adjacent organs such as the intraorbital structures (Fig. 16-15). The frontal sinuses are most commonly affected, accounting for approximately 60% of all mucoceleles.⁴⁵ The ethmoid sinuses account for approximately 25% of all mucoceleles. The maxillary sinuses account for approximately 10%, and the remaining 1% or 2% are the rare sphenoid sinus mucoceleles.⁴⁵ The presenting symptoms are those of mass effect with proptosis or cosmetic deformity. Pain is rare unless the mucocele is infected, in which case it is referred to as a mucopyocele.

On CT scans, a mucocele appears as an expanded sinus filled with homogeneous material of fairly low attenuation (~15 HU) (Fig. 16-16). As one would expect, on MRI studies most mucoceleles are isointense to soft tissue such as adjacent brain on T1-weighted images and show increased signal on T2-weighted images because of their high water content. However, a mucocele that has been present for many months may be of low signal on T2-weighted images and may even produce a signal void. This may be because of the high concentration of proteinaceous secretions and the slow resorption of water through the mucosa.^{7, 39,40}

Neoplastic Processes

Papillomas (Fig. 16-17)

The mucosa of the sinonasal cavity is ciliated columnar epithelium containing mucus-secreting glands called *Bowman's glands*. This unique mucosa is of ectodermal origin and gives rise to a distinct class of lesions with a hyperplastic zone of basement membrane enclosing epithelium that in some patients falls inward on itself, forming a polyp with an irregular or verrucous surface. These lesions are known as *papillomas* and are important to differentiate from simple cysts and polyps of the sinonasal cavity because of the possibility of malignant degeneration within the papillomas.^{2,45} Fungiform papillomas make up approximately half of all papillomas. These nearly always arise from the nasal septum, are usually solitary and unilateral, and may have an irregular surface much like that of other papillomas but are not considered premalignant. Fungiform papillomas must therefore be differentiated from inverted papillomas or endophytic papillomas, which make up approximately 50% of all sinonasal papillomas. These tend to occur in middle-aged men, characteristically arise from the lateral nasal wall in the region of the root of the middle turbinate, and may extend laterally into the paranasal sinuses, especially the maxillary sinus.

The most common presenting symptoms are nonspecific, including nasal obstruction, epistaxis, and anosmia. The rate of malignancy associated with inverted papillomas is approximately 15%. Although inverted papillomas most often have degenerated into squamous cell carcinomas, other tumors such as mucoepidermoid and adenocarcinomas have been reported.

Figure 16-15. Mucocoele. Sixty percent of mucocoeles occur in the frontal sinus. *A*, An expansile mass is shown arising from the left frontal sinus with destruction of the lateral wall of the left frontal sinus (*arrow*). *B*, A slightly more superior image in the same patient depicts dehiscence of the posterior wall of the left frontal sinus (*arrow*), which is also the anterior wall of the anterior cranial fossa. *C*, An anterior ethmoid mucocoele is shown with lateral expansion into the right orbit and dehiscence of the right medial orbital wall (*large arrow*). There is medial displacement of orbital contents such as the medial rectus (*small arrow*), leading to diplopia. Mucocoeles may be the result of sinus obstruction from either inflammation or tumor. *D*, Postcontrast sagittal T1-weighted image (TR500, TE32) in the midline. There is solid enhancement in the region of the ethmoid air cells (*long arrow*), peripheral enhancement with central secretions within the sphenoid sinus (*short arrow*), and a mucocoele with linear peripheral enhancement secondary to sinus obstruction from tumor.

Carcinoma

Squamous cell carcinoma of the sinonasal cavity arises most commonly from the maxillary sinus. This structure is involved in at least 80% of all patients with squamous cell carcinoma at some point in their course.³ These lesions occur primarily in men in the 6th and 7th decades of life. Most are low-grade tumors that arise from the nasal septum near the mucocutaneous junction. Because of the paucity of symptoms or mild symptoms, these tumors are often misdiagnosed or go undiagnosed with such chronic complaints as sinusitis, polyposis, and lacrimal duct obstruction until a mass in the oral cavity or cheek is noticed. The 5-year survival is approximately 25% to 30%.³ The main cause of unsuccessful response is local recurrence. When examining post-treatment patients, one may encounter radiation-induced changes. These can be differentiated from local recurrence (Fig. 16-18). The primary pathologic and therefore imaging feature of these lesions is propensity to destroy bone even in the presence of a relatively small demonstrable mass.

Because of the similarity in density of squamous cell

carcinoma and other carcinomas to adjacent secretions within obstructed sinuses, a small region of bony abnormality and apparent destruction is important for the early imaging diagnosis of carcinoma, especially squamous cell carcinoma. The use of IV contrast injection for CT scanning is rarely useful for differentiating tumor from inflammatory conditions or masses within the sinuses. The tumors themselves tend to enhance very little, whereas inflammatory mucosa may sometimes enhance brightly. However, the data suggest that enhanced (gadolinium [Gd-DTPA]) MRI examinations may be most useful for differentiating neoplastic from inflammatory masses within the paranasal sinuses when this diagnosis is in doubt¹⁷ (Fig. 16-19).

Approximately 10% of tumors of the sinonasal tract are glandular in origin. These include tumors that arise from minor salivary glands such as adenoid cystic carcinomas and mucoepidermoid carcinomas. They also include adeno-carcinomas.^{2, 3, 45} Adenoid cystic carcinomas are unusual because of their course. Many tend to recur many years following their initial diagnosis and treatment. These lesions also tend to spread along perineural sheaths and to

Figure 16-16. Imposters. *A*, Sagittal T1-weighted (TR500, TE32) image in the midline. Increased signal is seen overlying the frontal sinus (arrow). This may represent fat, hemorrhage, or a paramagnetic substance in a metastatic tumor such as a melanoma. The accompanying coronal CT image (*B*) shows a nonpneumatized and nondeveloped right frontal sinus. The marrow signal from this right frontal sinus was thought to produce the abnormal signal on the MRI study in *A*. *C*, Non-contrast-enhanced axial CT scan through the maxillary sinuses in a patient with sickle cell disease. The speckled pattern overlying the maxillary sinuses proved to be hyperactive marrow within the maxillary sinuses.

Figure 16-17. Papillomas. *A*, Polypoid soft tissue mass is shown based on the nasal septum (arrow), which proved to be a fungiform papilloma on biopsy. *B*, Polypoid soft tissue mass is shown based on the lateral nasal wall (arrows). This is a biopsy-proven inverted papilloma. Distinguishing between these two lesions is important because of the malignant potential of the inverted papilloma.

Figure 16–18. Radiation changes. These are MR images through the brain of a patient 18 months after radiation therapy for carcinoma in the paranasal sinuses. The T2-weighted image (A) reveals the presence of abnormal increased signal (arrow) in the frontal lobe white matter. The corresponding T1-weighted contrast-enhanced images (B and C) reveal nodular enhancement bifrontally (arrows). PET scans were negative. These lesions represent radiation-induced demyelination.

Figure 16–19. Squamous cell carcinoma. A, On this coronal T2-weighted image (TR3000, TE60), structures containing water, such as cerebrospinal fluid and inflammatory polyps, in the left maxillary sinus are of increased signal intensity. More cellular masses such as skeletal muscle and the mass within the inferior meatus on the left (arrow) are of more intermediate signal intensity. Cellular masses within the nasal cavity and sinonasal tract should be suspected of being neoplasms. B, The accompanying post-contrast-enhanced T1-weighted image (TR500, TE32) shows the expected surface linear enhancement on the inflammatory polyps in the left maxillary sinus (arrow). The turbinates and normal nasal mucosa enhance brightly inhomogeneously. The suspected nasal mass enhances somewhat less intensely than the normal turbinates. This is a biopsy-proven squamous cell carcinoma.

leave normal skip areas between the primary lesion and a local metastatic site along a nerve. This is often the case when a tumor arising in the maxillary sinus gains access to the mandibular nerve and extends toward the skull base.

At the time of radical antrectomy, the surgeon may be informed that the frozen sections showed no evidence of tumor. Some studies indicate that in many cases there has already been distant regional metastasis into the cavernous sinus at the time of surgery with an intervening normal segment of the trigeminal nerve. It has become the role of the imaging specialist, therefore, to evaluate the cavernous sinus and the more proximal portions of the trigeminal nerve in such patients to establish proper staging before radical and disfiguring surgery is undertaken.

Most adenocarcinomas arise from the ethmoid air cells and are especially common in hardwood workers and Bantu Indians.

A biopsy specimen revealing adenocarcinoma must be considered to represent a metastasis to the head and neck from kidney, lung, breast, or digestive tract until a metastatic workup is negative.

Olfactory Neuroblastoma⁴²

The olfactory neuroblastoma or esthesioneuroblastoma is an uncommon tumor that originates from neural crest cells and arises from the olfactory mucosa. The incidence curve for this disease has a bimodal shape, with the first peak in the 2nd decade and the 2nd peak in the 6th decade. This polypoid tumor may be soft or firm but may be friable and bleed profusely.

A unique feature regarding olfactory neuroblastomas and the importance of these lesions to the imaging physician concerns its unique site of origin and pathway of spread. The mass may be relatively slow-growing for a malignant tumor and may cause some expansion and remodeling of bony structures. It may therefore be mistaken for benign disease. On the other hand, the tumor has a propensity for intracranial extension through the dura in the region of the cribriform plate. A change in surgical

philosophy now dictates that a craniofacial resection should be performed as the initial procedure in all patients. With this protocol, cure rates have approached the 90% survival mark. Before this approach, recurrence neared 50%, with metastasis in approximately a third of patients (Fig. 16–20).

Lymphoma

Lymphomas represent the most common sarcomas involving the sinonasal tract.⁹ The majority of these are non-Hodgkin's types of lymphomas. Non-Hodgkin's lymphoma is the second most common malignancy of the head and neck following squamous cell carcinoma. It is important to try to recognize lymphoma as distinct from squamous cell carcinoma because of its different clinical course and the marked radiosensitivity of lymphomas relative to squamous cell carcinoma. Grossly, these tend to be bulky soft tissue masses that may enhance following gadolinium injection and tend to remodel bone and occasionally erode bone rather than destroy bone.¹⁹ The nasal cavity and maxillary sinus are the most common sites of origin.

Benign Tumors

One of the most important benign tumors of the sinonasal structures—although by no means the most common benign tumor in this region—is the juvenile angiofibroma or nasopharyngeal angiofibroma (Fig. 16–21). This is a highly vascular and nonencapsulated polypoid mass that is histologically benign but highly aggressive.⁴ It occurs almost exclusively in males in the second decade of life, who present with nasal obstruction and severe epistaxis as well as facial deformity and proptosis. The site of origin is thought to be the nasopharyngeal region at the pterygopalatine fossa or sphenopalatine foramen. Involvement of the pterygopalatine fossa is seen in approximately 90% of patients as asymmetry in the size or widening of this structure and an absence of the normal fat plane between

Figure 16–20. Esthesioneuroblastoma. This unique tumor arises from the olfactory mucosa in young adults. It typically spreads anteriorly into the orbital apices and posteriorly into the suprasellar region. The left carotid artery is encased (A) (arrow). There is also inferior extension into the nasal cavity as seen in the post-contrast-enhanced coronal image (B) (arrow).

Figure 16-21. Juvenile angiofibroma. Axial post-contrast-enhanced CT scan (A) through the paranasal sinuses reveals an enhancing mass within the infratemporal fossa (arrows) that extends into and expands the pterygopalatine fissure (arrowhead). In the coronal view (B) there is extension into the nasal cavity with destruction of the pterygoid plates and extension into the sphenoid sinus. There is also lateral extension into the region of the cavernous sinus with bone destruction (arrow). These masses are usually supplied by terminal branches of the sphenopalatine artery (C, long arrow). In this particular patient, because of the extension intracranially, there is supply from dural vessels such as the middle meningeal artery (C, short arrow). In addition, there is also supply from other external carotid branches such as the ascending pharyngeal (D). In patients with intracranial extension or with extension into the clivus, there may be supply from branches of the internal carotid artery (E, arrow).

the pterygoid plates and the back of the maxillary sinus.⁴⁶ The tumor may extend anteriorly and superiorly into the maxillary and ethmoid sinuses or superiorly into the cranial fossa. There is also the possibility of extension superiorly through the inferior orbital fissure into the orbit and then through the superior orbital fissure into the brain.

Because of the extreme vascularity of the tumor and propensity for profuse hemorrhage, the imaging physician must recognize this entity when it occurs and should strongly discourage biopsy. Ultimately, an arteriogram should be performed to demonstrate the major feeding vessels, which are most often the internal maxillary artery

and ascending pharyngeal artery. Preoperative embolization of these branches of the external carotid artery may greatly reduce blood loss at surgery, allowing for a more careful dissection and, therefore, complete resection in addition to minimizing the risk of multiple transfusions. Contrast-enhanced CT or MRI examination reveals a polypoid and infiltrating enhancing mass that involves the nasopharynx and pterygopalatine fissures and extends anteriorly into the nasal cavity, maxillary sinuses, and ethmoid sinuses.⁴⁵ Again, the orbits and cavernous sinuses may be involved.

The treatment of choice is surgical resection. The role of radiation therapy is not clear, although control of tumor growth has been reported. The use of estrogen therapy is also recommended.² Many of these tumors begin to involute toward the end of puberty, and the goal of therapy is to minimize facial deformity and bone destruction and to minimize the need for transfusions and the occurrence of fatal epistaxis, until the tumor begins to involute and fibrose as part of its natural history. There is no premalignant potential.

Neurogenic Tumor³⁴

Schwannomas are benign, encapsulated, slowly growing tumors of the nerve sheath that occur in patients from the 4th to 7th decades. Few have been reported within the sinonasal cavity, although a fairly sizable proportion do occur in the head and neck. These are slow-growing expansile lesions that are important for one to recognize as differential diagnostic possibilities when faced with a similar sinonasal mass. Most importantly, they may mimic juvenile angiofibromas by bowing forward the posterior wall of the maxillary sinus. They do not, however, usually involve the pterygopalatine fissure and by that observation may be differentiated from juvenile angiofibromas in younger patients.

Neurofibromas also occur in the head and neck. These are hamartomatous lesions associated with neurofibromatosis I. Some of these may not be differentiable from schwannomas in the head and neck. When plexiform neurofibromas arise from the soft tissues or subcutaneous tissues, they may infiltrate from superficial to deep within the paranasal sinuses. At times these may be aggressive and destructive and mimic malignant tumors.

Fibro-osseous Lesions⁴⁵

Fibro-osseous lesions are probably the most common noninflammatory benign masses of the sinonasal region. Of all the nonepithelial tumors of the paranasal sinuses, approximately 25% are thought to be fibro-osseous in origin.

One of the more common incidental findings, which is a fibro-osseous lesion, is the osteoma (Fig. 16-22). This benign proliferation commonly occurs within the frontal sinus and may cause obstruction or directly erode from the frontal or ethmoid sinus into the cranial cavity, causing a spontaneous cerebrospinal fluid (CSF) leak. These are often described as “ivory” or highly dense bone, which is obvious on both plain film and CT examinations. Osteomas

Figure 16-22. Osteoma. The densely calcified nodular structure at the base of the left frontal sinus (arrow) is an osteoma. This is a common benign tumor within the anterior ethmoids or inferior frontal sinuses and may cause spontaneous cerebrospinal fluid rhinorrhea.

may be small incidental findings on plain film or CT scans but may obstruct the frontal sinuses and again cause CSF rhinorrhea. When multiple osteomas are seen—especially when the skull and mandible are primarily involved—one should entertain the diagnosis of Gardner's syndrome, and investigation of the gastrointestinal tract should be undertaken in a search for intestinal polyps (Box 16-5).

Fibrous dysplasia⁶ is an idiopathic disorder in which the medullary bone is replaced by a poorly organized and loosely woven bone that is also expanded compared with normal adjacent bone (Fig. 16-23). The monostotic type is the most common, involving approximately 75% of all patients. In approximately 25% of the patients, bones of the head and neck are involved, with the maxilla and mandible being the most common sites. Polyostotic fibrous dysplasia accounts for approximately one quarter of all cases of fibrous dysplasia. There is a small potential for

Figure 16-23. Fibrous dysplasia. Polyostotic or monostotic fibrous dysplasia frequently occurs in the facial bones. This axial CT scan through the skull base shows monostotic fibrous dysplasia affecting the pterygoid bones on the right (arrow).

Glomerulonephritis

Figure 16-24. Osteopetrosis. A, A frontal radiograph of the sinuses in a 1-year-old girl reveals the classic sclerotic and chalky appearance of the facial bones and orbits. B and C, Axial and coronal CT scans also show the typical appearance of this rare disease with thickened sclerotic bone and secondary obstruction of the sinuses.

Figure 16-25. Ossifying fibroma. An expansile mass with calcified matrix forming arches or rings is indicative of a benign primary bone tumor. With expansion and destruction, a more aggressive process must always be suspected such as a chondrosarcoma or osteogenic sarcoma.

malignant transformation (~0.5% of patients). This most often occurs in the polyostotic form. Radiographically, the affected bones are noted to be abnormal because of their texture. There is a ground-glass or ivory appearance of the affected bone with expansion of the middle table blending into the inner and outer tables. Osteopetrosis rarely occurs in the paranasal sinuses (Fig. 16-24).

The ossifying fibroma, unlike fibrous dysplasia, contains a lamellar rather than woven pattern of bone and has a normal number of osteoblasts and osteoclasts (Fig. 16-25). Internal regions of disorganization with discrete zones contain either osseous issue or fibrous tissue. Pathologically, the differential diagnosis from fibrous dysplasia is difficult, whereas from an imaging standpoint the differential diagnosis is often much easier.

Giant cell tumors⁴³ or osteoclastomas make up approximately 5% of all primary bone lesions. Most of these are located in the epiphyseal regions of the long bones, especially around the knee. Approximately 2% of all giant cell

tumors, however, occur in the head and neck. These may be located in the region of the sphenoid temporal bone or ethmoid sinuses. Approximately 10% to 15% of giant cell tumors have histologic evidence of malignancy, and these lesions should be irradiated following complete surgical excision. From an imaging point of view, these tumors are lytic lesions with narrow zones of transition. A high index of suspicion is necessary on the part of the imaging physician to raise this diagnosis early so that aggressive surgery and radiation therapy can be undertaken.³⁸

Odontogenic tumors that arise from the alveolar ridge may extend to the maxillary sinus.³⁷ Approximately 10% to 15% of all maxillary sinus inflammatory and neoplastic diseases have an odontogenic origin. A high index of suspicion is required on the part of the imaging physician when confronted with a suspicious mass within the maxillary sinus; coronal examinations should be done to evaluate the possibility of extension of a cyst or mass from the alveolar ridge into the maxillary sinus (Fig. 16-26).

The most common odontogenic lesions involving the maxillary sinus are *odontogenic cysts*.²⁶ These fall into three broad categories.

Primordial cysts represent approximately 5% of odontogenic cysts and are thought to arise from a supernumerary tooth germ in a patient with an otherwise normal complement of teeth. These are cystic masses that expand from the alveolar ridge superiorly into the maxillary sinus. They are unassociated with either normal or abnormal tooth buds.

Dentigerous cysts represent approximately 95% of follicular cysts and are thought to arise from an unerupted tooth after the crown of the tooth has been developed.⁴³ The crown of the affected tooth projects into the cystic mass, and the roots of the unerupted tooth project centrifugally from it. These are unilocular and grow slowly, loosening and disrupting the relationship of adjacent teeth. They may also present as cystic masses within the maxillary sinus. These *periodontal* or *radicular cysts* are also known as *periapical abscesses* or *granulomas* and are the result of inflammatory changes at the tooth root associated with dental caries.

Other unusual tumors of the upper molar teeth include

Figure 16-26. Odontogenic mass. On the Waters view of the paranasal sinuses, a teardrop-shaped density was identified in the right maxillary sinus (A, arrow). The accompanying coronal CT image (B) revealed an expansile mass containing multiple teeth.

Figure 16-27. Inferior orbital wall fracture. Coronal CT scan reveals a fracture in the inferior wall of the right orbit with downward displacement of the fragment (*curved arrow*) but without herniation of the orbital contents.

multilocular ameloblastoma and the highly dense cementoma. These are beyond the scope of this chapter.

Trauma⁴⁵

Because of extensive overlying edema, hemorrhage, and soft tissue injury, the deformity of the underlying facial skeleton is often concealed at the time of presentation to the emergency department following trauma. There may be subtle clinical signs such as palpable stepoff of the orbital rim, hypertelorism, midface elongation, or CSF rhinorrhea. Radiographic examination is key to the diagnosis of facial and orbital fractures on a timely basis so that these lesions can be treated along with other potentially life-threatening injuries.^{15,32}

Before imaging evaluation of the patient with suspected facial fractures, or to rule out such fractures, one should evaluate the cervical spine for fracture and/or instability on both a clinical and imaging protocol. When it has been

established that the patient can cooperate for coronal examination and is stable regarding other injuries that may have been sustained, axial and coronal noncontrast CT examination through the paranasal sinuses is recommended in all instances.

Nasal Bone

Fractures of the nasal bone are the most common fracture of the facial skeleton.³⁶ These may be isolated or associated with other injuries. Plain film examination with oblique cone-down views of the nasal bones is the most sensitive study for identifying and mapping these lesions. In children, when the intranasal suture is not yet ossified, dislocation of the cartilaginous portion of the nose is more common. In adults, when the nose is struck, linear fracture traversing the long axis of the nose is the expected lesion.

Orbit

A blow to the orbit most often strikes the inferior orbital rim. It is now thought that the relatively thick rim of the orbit has elastic properties that allow it to bend posteriorly and rebound anteriorly following trauma. During this posterior excursion of the inferior orbital rims, however, there may be wrinkling and then crumbling of the floor of the orbit.¹² There is a groove within the floor of the orbit (the groove for the infraorbital nerve) that acts as a fault line, allowing orbital floor fractures to occur as the most common isolated fracture of the orbit. With more extensive force, there may be fracture of both the inferior orbital rim and the orbital floor. The former lesion is known as a "pure" blowout fracture, whereas the latter lesion, involving the inferior orbital rim, is known as a "impure" blowout fracture (Fig. 16-27).

Although the medial orbital wall, the lamina papyracea, is the thinnest bone in the body, it is supported by laterally and medially running septa of the ethmoid air cells. These act as struts between free segments of the lamina papyracea to prevent medial orbital blowout. Fractures through the

Figure 16-28. Trimalar fracture. On the axial view the trimalar fracture (*A*, *arrow*) is manifested as fractures of the anterior sinus wall and posterior sinus wall. *B*, Fracture of the ipsilateral zygomatic arch is shown.

Figure 16–29. Le Fort fractures. The unifying fracture among all types of Le Fort fractures is fracture through the pterygoid plates (A, arrow). Le Fort I fractures are rare. With Le Fort II types, the medial orbital wall (B, long arrow) is fractured, with continuation of the fracture line through the floor of the orbit and into the pterygoid plates. A Le Fort III fracture (B, short arrow) extends from the medial wall of the orbit to the lateral orbital wall and then inferiorly through the pterygoid plates.

medial orbital wall still occur either through transmission from direct trauma to the nose or from increased intraorbital pressure. Blowout fractures of the orbital roof also occur. Again, these may be caused by transmitted force through the superior orbital rim. More often they are the result of extension of fracture elsewhere in the skull into the superior orbital rim.

Side of the Face

Trauma to the side of the face or lateral orbital rim may result in the familiar tripod or trimalar fracture²⁸ (Fig. 16–28). This is a complex fracture involving the floor of the orbit, the anterior and posterior walls of the maxillary sinus, the zygomatic arch, the zygomaticofrontal suture, and the posterior wall of the orbit. Although it actually has at least four points, in any single plane it may appear as a three-pointed fracture fragment; thus, the eponyms are tripod and trimalar.

Le Fort Fractures

The unifying feature of Le Fort fractures is disruption of the pterygoid plates.³⁵ Because of the associated disruption of the pterygoid venous plexus, it is important to recognize these fractures as potentially life-threatening because of the relatively large nasopharyngeal hematoma that sometimes occurs.

There are three types of Le Fort fractures:

The *Le Fort I* fracture is a horizontal fracture above the hard palate with separation of the hard palate and lower portion of the pterygoid plates from the rest of the facial infrastructure.

The *Le Fort II* fracture begins at the bridge of the nose and extends laterally along the medial wall of the orbit and then inferiorly along the inferior wall of the orbit, through the anterior wall of the maxillary sinus, and then posteriorly through the alveolar recess of the maxillary sinus into the pterygoid plates.

The *Le Fort III* fracture also begins as a fracture through the base of the nose or glabella and extends along the medial wall of the orbit, much as the *Le Fort II* fracture does. Rather than extending into the floor of the orbit, however, there is extension of the fracture line along the lateral wall of the orbit, inferiorly through the maxillary sinus and then posteriorly through the pterygoid plates (Fig. 16–29).

Cervical Adenopathy and Neck Masses

Roy A. Holliday, Deborah L. Reede

High-resolution computed tomography (CT) and magnetic resonance imaging (MRI) have proved to be invaluable tools for evaluating the soft tissue structures of the neck. Although many imaging modalities are available for the evaluation of a neck mass, including radiography, ultrasonography, angiography, and radioisotope imaging, CT and MRI provide anatomical detail that cannot be obtained with these other modalities. CT and MRI demonstrate both the precise location of a neck mass and its relationship to adjacent vascular, muscular, and neural structures. In addition to providing this anatomical detail, CT and MRI frequently are able to characterize the vascularity and internal architecture (solid versus cystic) of a neck mass.

The combination of soft tissue characterization and anatomical localization afforded by CT and MRI allows radiologists to make a substantial contribution to the preoperative assessment of the patient with a neck mass. Although an exact tissue diagnosis is not always possible, careful analysis of the imaging features of a neck mass in combination with clinical history and physical examination produce a reasonably short differential diagnosis in nearly every case.

Imaging Technique

CT imaging of the neck is performed with the patient supine on the scanner gantry. Contiguous 5-mm-thick axial images are usually obtained from the level of the superior orbital rim to the lung apex. Care must always be taken to avoid image degradation by dental amalgam. One common solution is to acquire images from the superior orbital rim to the hard palate with the use of gantry angulation parallel to the central skull base. Images from the alveolar ridge of the mandible to the lung apex are then obtained with a gantry angulation parallel to the body of the mandible. If the patient's chin is fully extended, this latter series may be obtained with a 0-degree gantry angulation.

Intravenous contrast enhancement is essential for CT examinations of the soft tissue of the neck, to facilitate both tissue characterization of neck masses and separation of neck masses from normal vascular structures. Most investigators recommend an initial rapid bolus of approximately 50 mL of contrast material administered over 1 to 2 minutes before image acquisition, followed by a steady rapid drip infusion of the remaining 100 to 150 mL during scanning. Power injectors, commonly used for abdominal or thoracic CT scanning, can be readily adapted for neck CT examinations. Contrast administration should be interrupted during changes in gantry angulation.

Optimal MRI of the neck requires the use of surface coils. Images of the suprahyoid neck may be obtained by placement of the patient well inside many standard head surface coils. Images of the infrahyoid neck require dedicated anterior neck surface coils, because the use of posteriorly placed cervical spine surface coils results in suboptimal images owing to signal drop-off.

Current MRI techniques involve acquisition of T1-weighted images in sagittal, axial, and coronal projections with corresponding T2-weighted images obtained in the projection that best depicts the lesion. Slice thicknesses of 4 to 6 mm with 1- to 2-mm intervals between slices are commonly used. The prolonged scan times of axial T2-weighted images often result in images of diminished diagnostic quality owing to gross patient motion as well as artifacts produced by swallowing, respiratory motion, and cardiac pulsations. To overcome these problems, rapid spin-echo techniques are often used to obtain T2-weighted images in shorter scan times.⁴⁹

Contrast administration is not essential in MRI of neck masses. The use of multiple pulse sequences and multiple projections is usually sufficient to differentiate neck masses from adjacent vascular structures. When contrast enhancement is required for tissue characterization, fat-suppressed T1-weighted images are commonly used, particularly in the assessment of cervical adenopathy.⁴⁷

Choice of Imaging Modality

MRI and CT should be considered complementary, rather than competitive, modalities for imaging neck masses. The advantages MRI offers over CT in imaging other parts of the body (multiplanar capability, lack of ionizing radiation, safer contrast agents) also apply to imaging the soft tissues of the neck. By comparison, CT examinations offer the advantages of superior assessment of osseous integrity, shorter examination time, wider patient access, and lower cost.¹² The authors prefer to use contrast-enhanced CT as the initial study to assess neck masses in adults. In children and in adults whose clinical status precludes the use of iodinated contrast material, MRI is the study of choice, although a limited noncontrast CT study may be required for the evaluation of osseous integrity. The remainder of this chapter reflects this preference and emphasizes the normal and abnormal CT appearance of the soft tissues of the neck.

Normal Gross Anatomy

The neck is composed of the posteriorly located nucha and the anteriorly located cervix. The *nucha*, which consists primarily of the vertebral column and its associated musculature, is discussed in detail in Chapter 19. For practical purposes, the *cervix* (which also means neck) can be thought of as a cylinder of soft tissue whose superior extent is a line connecting the occiput and the tip of the chin and whose inferior extent parallels the course of the first rib at the thoracic inlet.¹³

The most important landmark to identify when one is studying the neck in any plane is the sternocleidomastoid muscle. The sternocleidomastoid muscle takes its origin from the mastoid tip and digastric notch at the skull base and extends anteriorly, inferiorly, and medially, spiraling across the anterior aspect of the neck on each side to insert as two heads on the medial third of the clavicle and the manubrium. The course of the sternocleidomastoid muscle is the basis for the division of the soft tissues of the neck into two paired spaces, the anterior and posterior triangles (Fig. 17-1). The sternocleidomastoid muscle forms the posterior border of the anterior triangle and the anterior border of the posterior triangle. All structures located anterior to the sternocleidomastoid muscle lie within the anterior triangle; those deep as well as posterior to it are in the posterior triangle.³² It is important to remember that no septum or fascial plane physically separates the anterior from the posterior triangle.

The anterior triangles have a common side, abutting each other in the midline. Their borders are the sternocleidomastoid muscle posteriorly, the mandible superiorly, and the midline medially. The hyoid bone divides this triangle

into a suprahyoid portion and an infrahyoid portion, each of which has two subdivisions.

The suprahyoid division contains the laterally located submandibular triangles and the medially located submental triangles. Superiorly these triangles are separated from the oral cavity by the mylohyoid muscle. This muscle forms a sling connecting the two inner surfaces of the mandible with the hyoid bone. By definition, structures above the mylohyoid muscle are in the oral cavity; those below are in the neck.

The base of each submandibular triangle is formed by the ramus of the mandible. The other two sides of each submandibular triangle are formed by the anterior and posterior bellies of the digastric muscle. The digastric muscle takes its origin from a depression on the skull base between the mastoid tip and the styloid process known as the *digastric notch*. The posterior belly of the digastric muscle extends anteriorly, inferiorly, and medially from the digastric notch to the greater cornu of the hyoid bone. The anterior belly of the digastric muscle extends from the greater cornu anteriorly, superiorly, and medially to insert on the anterior border of the mandible, inferior to the attachment of the mylohyoid muscle.

The major structures contained within the submandibular triangle are numerous small lymph nodes and the submandibular salivary glands. The anterior surface of the submandibular gland abuts the posterior free margin of the mylohyoid muscle, so a small portion of each submandibular gland lies within the posterior oral cavity but the majority of the gland lies within the suprahyoid neck.

The base of the submental triangle is formed by the hyoid bone. The other two sides of the submental triangle are formed by the anterior bellies of the digastric muscles. No major anatomical structures are located in this triangle except for a few small lymph nodes and branches of the facial artery and vein.

The infrahyoid division of the anterior triangle is divided by the superior belly of the omohyoid muscle into two parts, the carotid triangle superolaterally and the muscular triangle inferomedially. The infrahyoid portion of the anterior triangle contains the larynx, hypopharynx, trachea, esophagus, lymph nodes, and thyroid and parathyroid glands.

The two sides of each posterior triangle are the sternocleidomastoid muscle anteriorly and the trapezius muscle posteriorly. The base of each triangle is formed by the clavicle. The inferior belly of the omohyoid muscle crosses the inferior aspect of the posterior triangle and divides it into two unequal parts, the occipital triangle anteriorly and the subclavian triangle inferiorly.

The major structures located within the occipital triangle are the spinal accessory nerve (cranial nerve XI) and its associated chain of lymph nodes. The major structures located within the subclavian triangle are the transverse cervical vessels and their associated chain of lymph nodes. Also present within the posterior triangle are the exiting cervical nerve roots, the cervical components of the brachial plexus, and nutrient vessels.

The internal jugular vein and its associated chain of lymph nodes closely parallel the deep surface of the anterior margin of the sternocleidomastoid muscle, thereby bridging the anterior and posterior triangles. The arterial and neural components of the carotid sheath, the common

Triangles of the neck. 1, Anterior belly of the digastric muscle; 2, posterior belly of the digastric muscle; 3, superior belly of the omohyoid muscle; 4, inferior belly of the omohyoid muscle; 5, sternocleidomastoid muscle; 6, trapezius muscle. A, Submental triangle; B, submandibular triangle; C, carotid triangle; D, muscular triangle; E, occipital triangle; F, subclavian triangle. (From Reede DL, Whelan MA, Bergeron RT: CT of the soft tissue structures of the neck. Radiol Clin North Am 22:239, 1984.)

carotid artery, the internal carotid artery, and the vagus nerve, also traverse the neck within the anterior triangle.³²

Normal Sectional Anatomy

The sternocleidomastoid muscle is a constant landmark that can always be identified on axial CT scans or MR images through the neck. As one progresses from superior to inferior, the location of the sternocleidomastoid muscle moves from a far lateral position to a paramedian position. With this change in position of the sternocleidomastoid

muscle comes a change in relative sizes of the anterior and posterior triangles. Superiorly the anterior triangle occupies the majority of the cross-sectional area of the neck because there is little space between the sternocleidomastoid and trapezius muscles. Inferiorly the posterior triangle occupies the majority of the cross-sectional area of the neck because there is little space between the anterior surface of the sternocleidomastoid muscle and the midline.

The mylohyoid muscle, the major landmark separating the oral cavity from the suprahyoid neck, is readily identified on both coronal and axial images. On axial images (Fig. 17-2A and B), the muscle appears in cross-section as

Figure 17-2. Normal sectional anatomy at the junction of the oral cavity and neck. A, Contrast-enhanced CT image at the level of the mandible. The sternocleidomastoid muscle is posterior to the parotid gland. B, T1-weighted MR image at a similar level in a different patient. Note the greater tissue contrast between the mylohyoid muscle and the submandibular gland on MRI. Coronal CT scan (C) and coronal T1-weighted MR image (D) demonstrate the anterior belly of the digastric inferior to the sling-shaped mylohyoid muscle. 1, Sternocleidomastoid muscle; 2, mylohyoid muscle; 3, submandibular gland; 4, internal jugular vein; 5, internal carotid artery; 6, posterior belly of digastric muscle; 7, parotid gland; 8, anterior belly of digastric muscle; 9, longus colli muscle.

Figure 17-3. Normal axial anatomy of the suprahyoid neck. T1-weighted MR image in same patient as Figure 17-2B. The submental triangle is located between the two anterior bellies of the digastric muscle. 1, Sternocleidomastoid muscle; 2, mylohyoid muscle; 3, submandibular gland; 4, internal jugular vein; 5, internal carotid artery; 6, posterior belly of digastric muscle; 8, anterior belly of digastric muscle; 9, longus colli muscle.

two separate muscle bundles medial to the mandible. As axial images are obtained from superior to inferior, the distance between the separate bundles decreases. The superior aspect of the submandibular gland is identified on axial images at the posterior margin of the mylohyoid muscle. On coronal images, the muscle has the configuration of a hammock suspended from the medial (lingual) surface of the mandible (Fig. 17-2C and D).¹²

Immediately inferior to the mylohyoid muscle, the anterior bellies of the digastric muscle can be identified (Fig. 17-3). Depending on the degree of angulation used on axial imaging, varying amounts of mylohyoid muscle can be seen projecting between the anterior bellies of the digastric muscle. The cervical portion of the submandibular gland lies lateral to each anterior belly of the digastric muscle. The posterior belly of the digastric muscle can usually be identified medial and posterior to the parotid gland, separating the gland from the contents of the carotid sheath.³²

The hyoid bone is the major bony landmark of the anterior neck (Fig. 17-4). The hyoid is best identified on axial CT images, where its central body and greater horns (cornua) appear in the midline as an “inverted U” approximately at the level of the C3-4 disk space. The carotid bifurcation is typically located at or near the level of the hyoid bone. The thyroid cartilage has an *inverted V* appearance on axial images. The superior third of the cartilage is not fused in the midline at the level of the thyroid notch. Immediately superficial to the two halves of

Figure 17-4. Normal axial anatomy at the level of the hyoid bone. **A**, Contrast-enhanced CT scan. Note that the normal retrofacial vein or proximal external carotid artery might be mistaken for a lymph node or other mass on a noncontrast examination. **B**, T1-weighted MR image demonstrates the same soft tissue and vascular anatomy without intravenous contrast. 1, Sternocleidomastoid muscle; 3, submandibular gland; 4, internal jugular vein; 5, internal carotid artery; 6, external carotid artery; 7, retrofacial vein; 9, longus colli muscle.

Figure 17-5. Normal axial anatomy at the level of the thyroid cartilages. *A*, CT scan. *B*, T1-weighted MR image. Note how the anterior margin of the sternocleidomastoid muscle is located anterior to the vertebral body. Compare with Figure 17-2*B*. 1, Sternocleidomastoid muscle; 2, strap muscle; 3, internal carotid artery; 4, internal jugular vein; 9, longus colli muscle.

the thyroid cartilage are the strap muscles (sternohyoid, sternothyroid, thyrohyoid, and superior belly of the omohyoid). The degree and pattern of ossification of the cartilages vary with the age and sex of the patient. Separation of nonossified cartilage from the overlying strap muscles is accomplished more easily with MRI than CT.

At the level of the thyroid cartilage (Fig. 17-5), the carotid sheath structures are situated along the anterior surface of the sternocleidomastoid muscle or slightly deep to it, posterior and lateral to the thyroid cartilage.

The superior cornua of the thyroid cartilage are easily identified as paired calcified structures located lateral to two of the extrinsic muscles of the spine, the longus colli muscles. The inferior cornua of the thyroid cartilage articulate with the posterior aspect of the cricoid cartilage.

The cricoid cartilage has a characteristic circular appearance on axial imaging. As with the thyroid cartilage, the degree of ossification of the cricoid varies with age. In adult patients, the cricoid cartilage appears on CT scans as a thin rim of calcification surrounding a lucent medullary center.³² On T1-weighted MR images, the cricoid appears as a ring of tissue isointense to fat.

At approximately the level of the cricoid cartilage (Fig. 17-6), the superior pole of the thyroid gland appears on axial images as a triangular soft tissue structure situated between the cricoid cartilage medially and the carotid sheath structures laterally. The normal gland enhances uniformly with iodinated intravenous contrast material.³² On noncontrast T1-weighted images, the gland is homogeneous in appearance and slightly hyperintense to skeletal muscle. The level of the cricoid cartilage also marks the point at which the omohyoid muscle crosses over the internal jugular vein.

Images at the level of the first tracheal ring (Fig. 17-7) demonstrate the lower poles of the thyroid gland and the adjacent carotid sheath structures. The sternocleidomastoid muscles have a paramedian position just superior to their insertions on the sternum and clavicle. The esophagus is

usually collapsed, lying posterior to the trachea and usually just to the left of the midline.

The posterior triangle of the normal suprascricoid neck appears as a fat-filled cleft containing a few small soft tissue structures representing nutrient vessels, lymph nodes, and nerves.³² Beginning at the level of the cricoid cartilage, the anterior scalene muscle can be identified in the medial aspect of the posterior triangle, posterior to the carotid sheath structures. The anterior scalene, which arises from the transverse processes of C3 through C6 and inserts on the superior and posterior surfaces of the medial first rib, lies directly anterior to the exiting trunks of the brachial plexus. At the level of the first tracheal ring, the brachial plexus is identified as a heterogeneous low-density or low-signal-intensity focus immediately

posterior to the anterior scalene muscle.

Evaluation of Cervical Adenopathy

Enlarged cervical lymph nodes are the most common cause of a neck mass in an adult. In patients older than 40 years, the enlarged nodes are most often secondary to metastatic carcinoma, usually from a primary neoplasm of the aerodigestive tract. In patients between the ages of 21 and 40, the enlarged nodes are most often secondary to lymphoma.³⁷ The optimal evaluation of cervical lymph nodes requires close attention to radiographic detail as well as an understanding of basic anatomical and pathologic principles of otolaryngology.

Anatomic Principles

Approximately 300 lymph nodes are located in the head and neck. The French anatomist Rouviere³⁴ divided these nodes into the following 10 principal groups (Fig. 17-8):³⁴

1. Occipital nodes.

Figure 17-6. Normal axial anatomy at the level of the cricoid cartilage and inferior cornua of the thyroid cartilage. *A*, CT scan. The asymmetry in the diameters of the internal jugular veins is a normal variant. *B*, T1-weighted MR image. 1, Sternocleidomastoid muscle; 2, thyroid gland; 3, internal carotid artery; 4, internal jugular vein; 8, trapezius muscle; 9, longus colli muscle.

2. Mastoid nodes.
3. Parotid nodes.
4. Facial nodes.
5. Submandibular nodes.
6. Submental nodes.
7. Sublingual nodes.
8. Retropharyngeal nodes.
9. Anterior cervical nodes.
10. Lateral cervical nodes.

The first six groups form a *lymphoid collar* at the junction of the head and neck. Each group is responsible for the primary lymphatic drainage of a different region of the neck, as follows:

Occipital: Scalp and subcutaneous tissues of the occiput and superior neck.

Mastoid: Parietal scalp and auricle.

Parotid: Forehead, temporal scalp, lateral face, posterior cheek, lateral gingiva, buccal mucous membrane, exterior auditory canal, and parotid gland.

Facial: Lateral eyelids, anterior cheek, midface.

Submandibular: Lateral chin, lower and upper lips, lower cheek, anterior nose, medial eyelids, gingiva, anterior tongue, floor of the mouth, and submandibular and sublingual glands.

Submental: Central chin, lower lip, anterior gingiva, anterior floor of mouth, and tip of tongue.

The sublingual nodes also drain the tongue and floor of mouth but are not always identifiable as a separate group. The retropharyngeal nodes are further divided into medial and lateral groups. The medial group lies in the midline of the suprahyoid neck directly posterior to the pharynx. Enlargement of the medial group of retropharyngeal nodes is most commonly seen in neonates and young children. The lateral group is located anterior to the longus colli and longus capitis muscles, medial to the internal carotid artery, in both the suprahyoid and the infrahyoid neck. The retropharyngeal lymph nodes primarily drain the nasopharynx and posterior oropharynx as well as the paranasal sinuses, middle ear, posterior palate, and nasal cavity.

The anterior cervical nodes are toward the midline of the infrahyoid neck, located between the two carotid

Figure 17-7. Normal axial anatomy at the level of the first tracheal ring. *A*, CT scan. *B*, T1-weighted MR image. Note the relative sizes of the fat-filled posterior triangles and the anterior triangle between the right and left sternocleidomastoid muscles. Compare with Figures 17-2*B* and 17-5*B*. 1, Sternocleidomastoid muscle; 2, thyroid gland; 3, internal carotid artery; 4, internal jugular vein; 5, anterior scalene muscle; 6, esophagus; 9, longus colli muscle.

Figure 17-8. Nodal chains of the neck. (From Reede DL, Bergeron RT: CT of cervical lymph nodes. *J Otolaryngol* 11:411, 1982.)

sheaths. There are two divisions to this nodal group. The superficial division lies on the anterior surface of the strap muscles, following the course of the anterior jugular vein. The deep division of the anterior cervical nodes (also known as the juxtavisceral nodes or anterior compartment nodes) is located anterior to the larynx, thyroid gland, and trachea as well as in the tracheoesophageal groove. Included in the deep division is the Delphian node, located in the cricothyroid membrane of the larynx. The deep division drains the supraglottic and infraglottic larynx, piriform sinuses, thyroid gland, trachea, and esophagus.

The lateral cervical group constitutes the primary nodes of clinical interest in head and neck malignancies because it serves as a common route of drainage for all of the major regional structures. Similar to the anterior cervical nodes, the lateral cervical nodes are divided into superficial and deep divisions. The nodes in the superficial division follow the course of the external jugular vein. The deep division of lateral cervical nodes is further subdivided into the spinal accessory, internal jugular, and transverse cervical chains.

The spinal accessory chain of nodes follows the course of the spinal accessory nerve (cranial nerve XI) in the posterior triangle of the neck, deep to the sternocleidomastoid muscle. The spinal accessory chain receives drainage from the occipital and mastoid nodes as well as the lateral portions of the neck and shoulders.

The internal jugular chain of nodes follows the course of the internal jugular vein. At the superior aspect of this chain under the skull base, it is impossible to separate the internal jugular chain from the superior aspect of the spinal accessory chain. As the internal jugular vein descends in the neck, it is crossed by two muscles, the posterior belly of the digastric muscle superiorly and the omohyoid muscle inferiorly. At each junction of muscle and vein, a single lymph node, larger than adjacent nodes, is present. The jugulodigastric node (also known as the sentinel or tonsillar node) receives the lymphatic drainage from the submandibular nodes as well as the palatine tonsil and lateral oropharyngeal wall. The jugulo-omohyoid node receives all of the lymphatic drainage of the tongue.

The internal jugular nodes (also known as the deep cervical nodes) are arranged either in series or in parallel interconnecting rows adjacent to the vein. The nodes drain the parotid, submandibular, submental, retropharyngeal, and some anterior chain nodes. Nodes superior to the point where the omohyoid muscle crosses the internal jugular vein are usually located anterolateral to the vein. Nodes inferior to this point may be located anterior, medial, or posterior to the vein. This infraomohyoid node also receives lymphatic drainage from the arm and superior thorax. Among the most inferior of the internal jugular nodes are the nodes of Virchow.

The transverse cervical chain of nodes (also known as the supraclavicular nodes) follow the course of the transverse cervical vessels. The nodes in this chain connect the inferior aspects of the spinal accessory, internal jugular, and anterior jugular chains. The transverse cervical chain also receives drainage from the subclavicular nodes, the skin of the anterolateral neck, and the upper chest wall.

Figure 17-9. Simplified nodal classification. Diagram of the head and neck in left anterior oblique projection. Palpable nodes are indicated with use of a simplified nomenclature of Roman numerals I through VII. See text for explanation. (From Som PM: Lymph nodes of the neck. *Radiology* 165:596, 1987.)

In an attempt to eliminate the variations in nodal terminology, a simplified nodal classification was proposed in 1981.³⁶ This classification divides the clinically palpable cervical nodes into seven groups, each designated by a roman numeral (Fig. 17-9), as follows:

- Level I: Submandibular and submental lymph nodes.
- Level II: Internal jugular chain from the skull base to the level of the carotid bifurcation.
- Level III: Internal jugular chain from the level of the carotid bifurcation to the level of the intersection of the chain with the omohyoid muscle.
- Level IV: Infraomohyoid portion of the internal jugular chain.
- Level V: Posterior triangle lymph nodes.
- Level VI: Nodes related to the thyroid gland.
- Level VII: Nodes in the tracheoesophageal groove and superior mediastinum.

It is important to remember that this system does not include all the cervical lymph nodes. Retropharyngeal nodes and transverse cervical nodes are not included. The system, however, is easily transferred to sectional imaging (Fig. 17-10). Because the carotid bifurcation is typically located at or near the level of the hyoid bone and the level of the intersection of the internal jugular chain with the omohyoid muscle is at the level of the cricoid cartilage,

Figure 17–10. Sectional imaging using simplified nodal classification. **A**, Axial contrast-enhanced CT scan demonstrates bilateral lymph nodes (*curved white arrows*) anterior to each submandibular gland. They are level I (submandibular triangle) lymph nodes. Note the lucent zone of fat eccentrically located in each node. These zones represent prominent nodal hila. Compare with Figures 17–12 and 17–26. **B**, Axial contrast-enhanced CT scan demonstrates a homogeneous 2.5-cm diameter lymph node (*asterisk*) in the left posterior triangle deep to the sternocleidomastoid muscle (*s*) and separate from the internal jugular vein (*v*), internal carotid artery (*a*), and posterior belly of the digastric muscle (*d*). This is a level V (spinal accessory chain) lymph node. Asymmetry in the appearance of right and left digastric muscles is secondary to slight skewing of the patient's head within the scanner gantry.

the following *axial levels* may be used in staging nodal disease at imaging (Fig. 17–11)⁴²:

Axial level II: Suprahyoid internal jugular chain.

Axial level III: Infrahyoid internal jugular chain above the cricoid cartilage.

Axial level IV: Infracricoid internal jugular chain.

Patients referred for imaging of cervical lymph nodes typically can be assigned to one of three categories. The first is a patient with a known malignancy of the head and neck in whom nodal staging is required. The second is a patient with a neck mass, already demonstrated by aspiration cytology to be metastatic squamous cell carcinoma, in whom no primary head and neck malignancy is identified. The third is a patient with a neck mass of uncertain origin.

Nodal Staging

CT remains the standard for assessing palpable and nonpalpable nodal metastases in patients with tumors of

the head and neck. Based on the work of Mancuso^{20,21} and others, the following criteria have been adopted by most centers:

1. Normal lymph nodes are often invisible on CT. When present, these nodes have an ovoid (lima bean) shape and are of homogeneous soft tissue density. Normal lymph nodes typically measure less than 1.0 cm in diameter.
2. Any node measuring more than 1.5 cm in diameter is abnormal. Reactive as well as neoplastic nodes may produce this pattern. Reactive adenopathy is most commonly encountered in submandibular and jugulodigastric nodes.
3. Any node with a central lucency, regardless of size, is abnormal (Fig. 17–12). Nodes with this CT appearance, often referred to as *necrotic*, are focally or completely replaced with tumor (typically, metastatic squamous cell carcinoma). Actual necrosis of nodal tissue is not commonly seen on pathologic examination. Care must be

Figure 17-11. Internal jugular chain lymph nodes. *A*, Axial contrast-enhanced CT scan at the level of the hyoid bone demonstrates a 2-cm-diameter lymph node (*asterisk*) medial to the left sternocleidomastoid muscle (*s*) and lateral to the left internal jugular vein. This lymph node is present at the junction of axial levels II and III. *B*, Axial contrast-enhanced CT scan at the level of the cricoid cartilage demonstrates a 2-cm-diameter lymph node (*asterisk*) immediately posterior to the left internal jugular vein (*v*). This lymph node is present at the junction of axial levels III and IV.

taken not to mistake the fatty hilum of a normal node for the abnormal lucency. The fatty hilum is located at the periphery of the node (see Fig. 17-10A).

4. Obliteration of fascial planes surrounding a node is abnormal. The CT appearance of “dirty fat” surrounding a node may be seen in cases of extranodal spread of tumor or inflammation as well as after surgery or radiation therapy to the neck. In general, extranodal spread of tumor tends to cause a more focal obliteration of fascial planes than the other processes. Correlation with clinical history is essential (see Fig. 17-26).³¹

Many centers with active head and neck tumor services have more stringent criteria for assessing nodal size. Expounding on the pathologic studies of van den Brekel, these centers consider all lymph nodes with a short axis greater than or equal to 1.2 cm significant.⁴⁵ An alternative system is to maintain the size criterion of 1.5 cm for submandibular and jugulodigastric nodes but to consider nodes at other levels that measure 1.0 cm or larger to be significant.⁴² When these criteria are used, approximately 80% of the enlarged (homogeneous) nodes are secondary to metastatic disease, and 20% are caused by reactive hyperplasia.³¹

When the extranodal changes described here obliterate fascial planes between a lymph node and adjacent structures (muscles, vessels), there may be clinical fixation of the node to these structures. The amount of fixation is subjective, depending on the individual examiner. It is difficult to predict solely on the basis of CT findings whether clinical fixation exists. The only sure sign of nodal fixation is if the structure in question is completely surrounded by a nodal mass. This point is particularly important in evaluation of the internal or common carotid artery.²⁴ Loss of definition of the vessel wall, with visualization of an otherwise normal lumen, is consistent with infiltration of the vessel wall (Fig. 17-13).

The utility of spin-echo MRI in evaluation of nodal disease remains limited. T1-weighted images usually provide good differentiation between intermediate signal nodes and the surrounding high-intensity fat, allowing for accurate measurement of nodal size. Assessment of central nodal necrosis is more difficult on MRI than on CT. Tumor cells within nodes tend to produce intermediate signal on T1-weighted and T2-weighted images, whereas areas of actual nodal necrosis usually appear as areas of low signal on T1-weighted images and of high signal on T2-weighted

Figure 17-12. Metastases to small lymph nodes. Axial contrast-enhanced CT scan obtained at a level between the hyoid bone and the cricoid cartilage demonstrates two lymph nodes (*white arrows*) in the left internal jugular chain, each measuring 1 cm in diameter with central hypodensity not equal to that of fat. Each of these level III lymph nodes demonstrates a *necrotic center*. Multiple small nodes deep to the left sternocleidomastoid muscle (*s*) have a homogeneous appearance.

images.⁴⁷ One practical solution is to consider any lymph node that is heterogeneous in appearance abnormal, but even this alternative can fail if the dynamic gray scale of the images is limited or the signal-to-noise ratio low.⁴²

The Unknown Primary

Approximately 5% of all patients with carcinoma and 12% of patients with head and neck carcinoma have nodal metastases as the sole presenting complaint.⁴⁰ In cases in which a head and neck malignancy is not appreciated by the otolaryngologist on initial clinical examination, knowledge of the pathways of nodal drainage, in combination with the ability of CT to detect nonpalpable pathologic lymph nodes, allows the radiologist to identify potential sites of neoplasm, particularly when the tumor is predominantly submucosal in nature.

Figure 17-14. The unknown primary. Axial contrast-enhanced CT scan demonstrates a clinically palpable pathologic lymph node in level III of the right internal jugular chain (*asterisk*). Flexible nasopharyngoscopy failed to demonstrate a primary neoplasm. CT examination demonstrates asymmetrical soft tissue density in the right paralaryngeal space. Direct laryngoscopy confirmed the diagnosis of squamous cell carcinoma of the laryngeal ventricle.

Figure 17-13. Extranodal spread of tumor. Axial contrast-enhanced CT scan demonstrates an irregular interface between the large left necrotic nodal mass and the cervical fat. Anteriorly, the overlying platysma is thickened and irregular (*curved white arrows*). Posterolaterally, there is extension through the platysma into the subcutaneous fat (*straight arrows*). This nodal mass was immobile or "fixed" on physical examination. Note how the mass engulfs the arteriosclerotic left internal carotid artery (*open black arrow*).

The location of the enlarged lymph node(s) should direct suspicion of the primary site of neoplasm as follows (Fig. 17-14)³¹:

- Level I: Oral cavity, submandibular gland.
- Level II: Nasopharynx, oropharynx, parotid gland, supra-glottic larynx.
- Level III: Oropharynx, hypopharynx, supraglottic larynx.
- Level IV: Subglottic larynx, hypopharynx, esophagus, thyroid.
- Level V: Nasopharynx, oropharynx.
- Levels VI and VII: Thyroid, larynx, lung.

Bilateral nodal disease is particularly common in tumors of the soft palate, tongue, epiglottis, and nasopharynx. Isolated nodal disease in the supraclavicular fossa is unlikely to be secondary to a malignancy of the aerodigestive tract; more likely sites are lung, breast, stomach, and thyroid.⁴²

Figure 17-15. Hodgkin's disease. Axial contrast-enhanced CT scan at the level of the first tracheal ring demonstrates multiple enlarged homogeneous lymph nodes filling the left posterior triangle. Lymph nodes adjacent to the internal jugular vein (V) are level IV nodes. Lymph nodes adjacent to the trapezius muscle (T) are level V nodes.

Neck Masses

Isolated nodal masses may mimic a wide variety of lesions in the neck, including masses of congenital, neural, and infectious origins. The key to limiting differential diagnosis is correlation with clinical history. Multiple masses in the neck are most likely secondary to nodal enlargement. Although aspiration cytology or excisional biopsy is necessary to confirm the diagnosis of nodal disease, identification of certain CT patterns of nodal disease facilitates clinical evaluation, as follows:

1. Large homogeneous lymph nodes are most commonly encountered in lymphoma, sarcoid, and infectious mononucleosis. CT cannot reliably differentiate Hodgkin's from non-Hodgkin's lymphoma (Fig. 17-15).³¹
2. Total or relatively uniform enhancement of an enlarged node is usually encountered in inflammatory processes. Exceptions to this rule include nodal involvement by Kaposi's sarcoma, thyroid carcinoma, and renal cell carcinoma (Fig. 17-16).
3. Calcification within lymph nodes is unusual. Most commonly, the calcific deposits are the result of prior granulomatous disease.²⁸ Metastatic papillary carcinoma of the thyroid is the most common cause of neoplastic nodal calcifications.⁴² In rare instances, metastatic or lymphomatous nodes may calcify after irradiation or chemotherapy.^{3,5}
4. The presence of multiple nodes with a variety of CT appearances (homogeneous, necrotic, enhancing, and calcified) is most compatible with granulomatous disease of cervical lymph nodes. In urban centers, tuberculosis is the most common cause (Fig. 17-17).²⁸ Thyroid carcinoma may also produce this spectrum of CT appearances.⁴²

Figure 17-16. Kaposi's sarcoma. Axial contrast-enhanced CT scan at the level of the anterior bellies of the digastric muscles demonstrates multiple, uniformly enhancing masses in the anterior and posterior triangles of the neck bilaterally, the largest identified in the left spinal accessory chain (asterisk). Multiple oropharyngeal lesions are also present (K).

Evaluation of Non-Nodal Neck Masses

The CT and MRI appearances of nodal and non-nodal neck masses often overlap. Careful attention to imaging

Figure 17-17. Tuberculous adenitis. Axial contrast-enhanced CT scan at the level of the thyroid cartilage demonstrates lymph nodes that are variably homogeneous (asterisk), necrotic (black arrow), enhancing (curved white arrow), and calcified (straight white arrow). The patient, who is 12 years old, has little ossification of the thyroid cartilages.

findings and correlation with clinical history are essential to correct diagnosis of a mass of developmental, inflammatory, vascular, neural, or mesenchymal origin.

Masses of Developmental Origin

The most common developmental mass identified on imaging is the branchial cleft cyst. This lesion is the result of incomplete obliteration of the first, second, third, or fourth branchial apparatus. The majority of these lesions arise from the second branchial apparatus, which forms the facial muscles, styloid process, pinna, and portions of the ossicular chain and muscles of the middle ear.² The second branchial cleft cyst most commonly identified at imaging is the Bailey type II cyst, which is secondary to persistence of the embryologic cervical sinus.² These type II second branchial cleft cysts often manifest as painless fluctuant masses along the course of the anterior margin of the sternocleidomastoid muscle. They most commonly manifest in patients between the ages of 10 and 40 years but may become clinically obvious at any age.³³

On contrast-enhanced CT (Fig. 17-18), a type II second branchial cleft cyst characteristically appears as a well-circumscribed, unilocular, low-density mass adjacent to the anterior margin of the sternocleidomastoid muscle. CT attenuation measurements of these and other cystic masses range from 10 to 25 HU.¹¹ On MRI (Fig. 17-19), the contents of the cyst are usually isointense with cerebrospinal fluid on T2-weighted images. On T1-weighted images, the cyst contents are usually hyperintense to cerebrospinal fluid and may even be hyperintense to skeletal muscle.¹⁸

The extent of rim enhancement of branchial cleft cysts is variable. Thick rim enhancement and indistinctness of fascial margins may occur if the cyst becomes infected.

Figure 17-18. Type II second branchial cleft cyst. Axial contrast-enhanced CT scan demonstrates a unilocular cystic mass with minimal rim enhancement along the anterior margin of the left sternocleidomastoid muscle (s) displacing the left submandibular gland (G) anteriorly.

Septations are uncommon and are usually found only in cases of previous infection or needle aspiration. Infected cysts may mimic necrotic jugular chain lymph nodes or cervical abscesses on both CT and MRI.

If sufficiently large, the type II second branchial cleft cyst displaces the carotid artery and jugular vein medially or posteromedially. In contrast, the type III second branchial cleft cyst courses between the external and internal carotid arteries.²

Cystic hygroma is the most common form of lymphagiomatous malformation occurring in the neck. Although there are multiple theories of pathogenesis for lymphagiomatous, most experts believe that cystic hygromas form because the primordial lymphatic sacs failed to drain into the veins, resulting in hugely dilated cystic lymphatic spaces.⁴⁶

Seventy-five percent of cystic hygromas occur in the neck, and 20% in the axilla. Cystic hygromas are usually isolated malformations in patients in whom the remainder of the lymphatic system is normal. They may occasionally be associated with a more generalized failure of lymphatic system development, as seen in cases of the 45,X chromosome karyotype (Turner's syndrome).⁴⁸

In contrast to branchial cleft cysts, cystic hygromas typically manifest at or shortly after birth. The clinical presentation is often characteristic: a painless, easily compressible mass that may transilluminate on physical examination. Patients are usually asymptomatic, unless there is significant airway obstruction.³³ Cervical cystic hygromas are most commonly found in the posterior triangle but can also occur in the floor of mouth, submental triangle, and submandibular triangles. Because up to 10% of cervical cystic hygromas may extend into the mediastinum, imaging is performed to assess the extent of the lesion and its relationship to adjacent structures before surgical resection.

On contrast-enhanced CT (Fig. 17-20), cystic hygromas are low density in appearance without peripheral rim enhancement. Larger lesions may be multiloculated and are

Figure 17-19. Type II second branchial cyst. A, Sagittal T1-weighted MR image demonstrates a well-circumscribed anterior triangle mass (asterisk) mildly hyperintense to muscle along the anterior margin of the sternocleidomastoid muscle (s). B, Axial T2-weighted MR image demonstrates a hyperintense mass along the anterior margin of the left sternocleidomastoid muscle (s). Compare with Figure 17-18.

often poorly circumscribed. In contrast to other cystic-appearing masses in the neck, cystic hygromas typically insinuate themselves between adjacent structures rather than displace vascular or muscular structures.³³

The multiplanar capability of MRI makes it the ideal imaging modality for evaluating cystic hygromas (Fig. 17-21). On T2-weighted images, the hygromas are isointense with cerebrospinal fluid. Their appearance on T1-weighted images is more variable, either hypointense or hyperintense to skeletal muscle, depending on the relative protein concentration of the lymph fluid and prior episodes of trauma or infection.^{18,38}

Thyroglossal duct cysts are the result of incomplete involution of an embryologic tract, the thyroglossal duct.

It is through the duct that the thyroid gland passes during its migration from the foramen cecum in the tongue to its final position in front of the trachea. If any portion of this epithelium-lined duct persists after birth, a cyst may develop. The hyoid bone is intimately associated with the thyroglossal duct during its development; a thyroglossal duct cyst may be located anterior to, posterior to, or within the hyoid bone.³⁰

Thyroglossal duct cysts account for approximately 70% of all congenital neck masses, with the overwhelming majority occurring in the pediatric age group. Routine sectional imaging of thyroglossal duct cysts is not performed in children because the clinical presentation (a painless midline neck mass that moves on swallowing) is so typi-

Figure 17-20. Cystic hygroma. Axial contrast-enhanced CT scan at the level of the first tracheal ring demonstrates a multilocular cystic mass without rim enhancement occupying the entire right posterior triangle extending toward the right axilla. S, Sternocleidomastoid muscle.

Figure 17-21. Cystic hygroma. A, Sagittal T1-weighted MR image demonstrates a lobulated posterior triangle mass (*asterisk*) that is moderately hyperintense to muscle and located deep to the posterior margin of the sternocleidomastoid muscle (s). Note how the hygroma tracks posterior to the internal jugular vein (V). B, The hygroma appears virtually isointense to fat in the right posterior triangle (PT), owing to window width and level.

cal.³³ Ultrasonography or radioisotope scanning may be performed to confirm a normal position of the thyroid before surgery.

CT or MRI is usually performed preoperatively in cases of suspected thyroglossal duct cyst in adults to confirm the diagnosis and to exclude other nodal masses. On contrast-enhanced CT, a well-circumscribed, low-density mass is present (Fig. 17-22).³⁰ Peripheral rim enhancement or internal septations are occasionally seen. The MRI signal characteristics of thyroglossal duct cysts are the same as those of branchial cleft cysts or small cystic hygromas.

Suprahyoid thyroglossal duct cysts are midline in location. The more common infrahyoid thyroglossal duct cysts often have both midline and off-midline components, the latter being embedded in the strap muscles. It is the location of an infrahyoid thyroglossal duct cyst in the strap muscles, not its signal or attenuation characteristics, that allows for a definitive radiographic diagnosis.³⁰ The presence of a solid mass along the thyroglossal duct should raise suspicion of ectopic thyroid tissue, in which occult malignancy is more likely.

Dermoid cysts are the rarest of the congenital neck

Figure 17-22. Thyroglossal duct cyst. Axial contrast-enhanced CT scan at a level immediately inferior to the hyoid bone demonstrates a cystic anterior triangle mass with peripheral rim enhancement (*asterisk*) embedded within the strap muscles to the right of midline. M, Left strap muscles; S, right sternocleidomastoid muscle.

Figure 17-23. Dermoid cyst. Axial contrast-enhanced CT scan demonstrates a mass with peripheral rim enhancement in the submental triangle. The mass contains a fatty component anteriorly and a fluid component posteriorly. D, Anterior bellies of the digastric muscles. The central portion of the hyoid bone is absent because of previous surgery to remove a thyroglossal duct cyst. (From Reede DL, et al: *Nonnodal pathologic conditions of the neck*. In Som PM, Bergeron RT (eds): *Head and Neck Imaging*, 2nd ed. St. Louis, CV Mosby, 1991.)

lesions. Only 7% of all dermoid tumors occur in the head and neck. The majority of head and neck dermoids occur in the orbit, nasal cavity, or oral cavity; true cervical dermoids are rare. The term *dermoid cyst* has been used to include the following three types of cysts: (1) epidermoids or epidermal cysts, (2) dermoids, and (3) teratoid cysts.^{22,33} These three types of congenital cysts can be differentiated histologically by the presence or absence of an epithelial lining and the cyst contents. Differentiation among the three types of dermoid cysts by sectional imaging is often impossible.

Most cervical dermoid cysts occur in the midline or just off-midline and are usually present at birth. In contrast to thyroglossal duct cysts, dermoid cysts typically do not move with swallowing. On CT, the presence of fat within the mass suggests a diagnosis of dermoid rather than epidermoid (Fig. 17-23). In the absence of demonstrable fat, epidermoids and dermoids cannot be distinguished by CT or MRI.

Masses of Inflammatory Origin

It is often difficult to determine clinically whether a patient with an erythematous, painful, and swollen neck has a simple cellulitis or a potentially life-threatening deep

neck abscess. With sectional imaging, it is possible not only to diagnose an abscess but also to differentiate it from cellulitis.^{12,33}

The CT characteristics of neck infections have been well described. Abscesses appear as single or multiloculated, low-density masses that conform to fascial spaces. When intravenous iodinated contrast agent is administered, abscesses demonstrate peripheral rim enhancement. Cutaneous and subcutaneous manifestations of infection are also seen. The manifestations include enlargement of adjacent muscles (myositis), thickening of the overlying skin, prominent linear densities within the subcutaneous fat, and enhancement of fascial planes. The presence of these cutaneous and subcutaneous manifestations without a low-density collection is consistent with cellulitis (Fig. 17-24).^{12,33}

A "characteristic" appearance of cervical infections on MRI has yet to be defined. In general, abscesses appear as single or multiloculated masses that are hypointense to skeletal muscle on T1-weighted images and markedly hyperintense on T2-weighted images. The use of MRI contrast agents should demonstrate an enhancing rim in a mature abscess. Differentiation of abscesses from other noninfectious masses on MRI requires careful attention to variations in the dynamic gray scale. Particular attention must be paid to window and level settings because subtle changes in cervical fat may be obscured by the hyperintense signal of cervical fat on T1-weighted images (Fig. 17-25).

No studies have yet compared CT and MRI in the evaluation of cervical infection. Several problems have been noted by investigators using MRI to evaluate inflammatory disease: First, the cutaneous manifestations of infection are not obvious on MR images; second, subcutaneous manifestations of infection may be obscured on MR images if imaging parameters are not carefully monitored; third, after intravenous administration of contrast agent, the enhancing rim may become isointense with surrounding fat, limiting detection or delineation of the abscess unless fat-suppression techniques are used; fourth, areas of abscess formation and cellulitis both tend to be hyperintense on T2-weighted images, hampering differentiation between the two processes.^{12,33}

The authors prefer the use of contrast-enhanced CT to assess suspected inflammatory disease in adults. In children and in adults whose clinical status precludes the use of iodinated contrast material, MRI is the study of initial choice, although a limited noncontrast CT study may be required for evaluation of osseous integrity. If MRI is not available, ultrasonography is an alternative modality for localizing suspected collections for surgical drainage.

Regardless of the modality used, the following important principles must be remembered:

1. Radiographic changes in the skin, fat, and fascial planes of the neck are not pathognomonic for an infectious process. Inflammatory reactions after radiotherapy or surgery can mimic cervical infections.
2. Radiographically, a necrotic tumor, nodal disease with extension into the adjacent soft tissues, and a thrombosed vessel may all mimic an abscess on sectional images (Fig. 17-26). Clinical correlation is essential.
3. Not every infectious process demonstrates the radio-

Figure 17-24. Abscess versus cellulitis. *A*, Axial contrast-enhanced CT scan demonstrates a low-density collection (*A*) in the anterior triangle surrounded by an irregular rim of contrast enhancement (*arrows*) consistent with abscess. *B*, Axial contrast-enhanced CT scan in a different patient demonstrates irregular linear densities in the fat of the anterior triangle (*C*). There is thickening of the platysma muscle (*black arrows*) and the skin (*white arrow*). No fluid collections are present. This image is compatible with cellulitis. (From Holliday RA, Prendergast NC: Imaging inflammatory processes of the oral cavity and suprahyoid neck. Oral Max Surg Clin North Am 4:215, 1992.)

graphic changes listed here. Granulomatous infections with *Mycobacterium* and occasionally *Actinomyces* species often appear as “bland” masses, without central necrosis or peripheral cellulitic changes.

4. Inflammatory lesions are always in a state of evolution. It is possible that a patient may be studied before a cellulitis has “ripened” to a frank collection of pus. If a diagnosis of cellulitis is made and the patient shows no response to appropriate antibiotic therapy, a second examination should be performed to ensure that an abscess cavity has not formed.^{12,19}

Once a diagnosis of cervical abscess is established, it is important to “map out” the sites of abscess accurately to ensure proper surgical drainage. Cervical infections frequently spread along the fascial planes within the neck. Abscesses are often located within a single compartment or “space” within the neck. The following summary of fascial anatomy is designed to facilitate mapping of cervical infections. It must be acknowledged that any classification of fascial anatomy is somewhat arbitrary because fasciae are simply the more obvious layers of the general connective tissue packing with the body. Nevertheless, the

following definitions are stressed in both the anatomical and the surgical literature (Figs. 17-27 and 17-28).

Two cervical fasciae exist, the superficial and the deep.^{10, 12, 17, 23, 26,41} The superficial cervical fascia is a layer of connective tissue that surrounds the head and neck, encircling the platysma muscle. The fascia also contains blood vessels, lymphatic channels, cutaneous nerves, and hair follicles. Its primary function is to allow the skin to glide easily over the deeper structures of the neck. Infections that track along the superficial cervical fascia are often secondary to skin infections and rarely track deeper into the neck.

The deep cervical fascia consists of three layers: the superficial layer, known as the investing fascia; the middle layer, known as the visceral fascia; and the deep layer, which has two divisions separated by a potential space—the alar layer anteriorly and the prevertebral layer posteriorly.

The investing fascia surrounds all the important structures of the neck. The visceral fascia surrounds the aerodigestive tract. The deep layer surrounds the vertebral column and paravertebral muscles. All three layers are closely

Figure 17-25. Abscess. *A*, Axial T1-weighted MR image demonstrates a mass (*asterisk*) in the right submandibular triangle that is hypointense to the anterior bellies of the digastric muscles. *B*, Corresponding axial T2-weighted MR image demonstrates hyperintense signal within the mass (*asterisk*). Note that inflammatory changes in the fat lateral to the abscess (*arrows*) are not as easily appreciated as on CT scans. (From Holliday RA, Prendergast NC: Imaging inflammatory processes of the oral cavity and suprahyoid neck. *Oral Max Surg Clin North Am* 4:215, 1992.)

Figure 17-26. Metastatic lymph node mimicking abscess. Axial contrast-enhanced CT scan demonstrates a low-density right submandibular triangle mass (*asterisk*) surrounded by an irregular rim of contrast enhancement. The overlying platysma muscle is thickened. The patient, who was afebrile, had a history of treatment for squamous cell carcinoma of the right oropharynx 2 years before this examination. Needle aspiration of the mass yielded atypical squamous cells.

Figure 17-27. The layers of deep cervical fascia and the cervical spaces, sagittal view. *Solid line*, investing fascia; *dotted line*, visceral fascia; *broken line*, prevertebral fascia. 1, Suprasternal space of Burns; 2, visceral space; 4a, retrovisceral component of the retropharyngeal space; 4b, danger space; 5, prevertebral space. M, mylohyoid muscle; THY, thyroid gland. (Adapted from Smoker WRK, Harnsberger HR: Normal anatomy of the neck. In Som PM, Bergeron RT (eds): Head and Neck Imaging, 2nd ed. St. Louis, Mosby Year Book, 1990, pp 498-518.)

associated in the anterolateral neck, where they all contribute to the formation of the carotid sheath, which surrounds the carotid artery, internal jugular vein, and vagus nerve.

The investing fascia is attached posteriorly to the ligamentum nuchae and the spinous processes of the cervical vertebral bodies. As it extends anteriorly, the fascia splits to envelope the trapezius and sternocleidomastoid muscles, forming the roof of the posterior triangle. In the suprahyoid neck, the fascia also splits to surround the parotid and submandibular glands before attaching to the body of the hyoid bone and the inferior surface of the mandible.

In the infrahyoid neck, the investing fascia splits to surround the strap muscles anterior to the larynx and trachea. The fascia also invests the omohyoid muscle, holding the muscle close to the clavicle, so contraction of the muscle results in a downward rather than a lateral pull on the hyoid bone. The investing fascia is attached superiorly to the external occipital protuberance, the mastoid process, and the skull base. It is attached inferiorly to the clavicle, the acromion, and the anterior and posterior surfaces of the sternum.

The visceral fascia extends from the central skull base to the mediastinum, encircling the pharynx, esophagus, larynx, and trachea. In the mediastinum, the visceral fascia blends with the pericardium, forming the anterior border of the retropharyngeal space. In the infrahyoid neck, the

Figure 17-28. The layers of deep cervical fascia and the cervical spaces of the infrahyoid neck, axial view. *Solid line*, investing fascia; *dotted line*, visceral fascia; *broken line*, prevertebral fascia. 2, Visceral space; 3, carotid space; 4, retropharyngeal space; 5, prevertebral space. CCA, common carotid artery; E, esophagus; IJV, internal jugular vein; SCM, sternocleidomastoid muscle; STR, strap muscles; THY, thyroid gland; TR, trachea; TRP, trapezius muscle. (Adapted from Smoker WRK, Harnsberger HR: Normal anatomy of the neck. In Som PM, Bergeron RT (eds): Head and Neck Imaging, 2nd ed. St. Louis, Mosby Year Book, 1990, pp 498-518.)

fascia is attached anteriorly to the cricoid and thyroid cartilages and splits to form the capsule of the thyroid gland.

The deep layer of the deep cervical fascia, like the investing fascia, begins in the posterior midline. The deep layer forms the floor of the posterior triangle, covering the paraspinal and scalene muscles. The deep layer is attached laterally to the transverse processes of the vertebral bodies, where it then splits into the anterior alar and posterior prevertebral layers as they extend anterior to the vertebral body. The alar and prevertebral layers have different craniocaudal extensions; although both attach superiorly at the skull base, the alar layer blends with the visceral layer along the posterior margin of the esophagus at the level of approximately T2, whereas the prevertebral layer extends more inferiorly anterior to the anterior longitudinal ligament.

The three layers of the deep cervical fascia delineate spaces in and through which bacterial infections can spread in the infrahyoid neck. The visceral space includes all structures within the confines of the visceral fascia and is continuous with the anterior mediastinum.

The retropharyngeal space is situated in the midline directly posterior to the pharynx. The anterior boundary of the retropharyngeal space is formed by the visceral fascia, and the posterior boundary is formed by the deep layer of the deep cervical fascia.

The retropharyngeal space can be further divided by the alar layer into the *retrovisceral space* anteriorly and the *danger space* posteriorly. Depending on its location, infection in the retropharyngeal space can extend inferiorly in

the retrovisceral space to the level of approximately T3 (where the alar layer and the visceral layer fuse) or in the danger space inferiorly to the level of the diaphragm. Because it is impossible to separate these two smaller spaces radiographically, the retropharyngeal space may be considered as a single radiographic space, with the recognition that all infections in the retropharyngeal space must be evaluated in full, and scans of either the superior mediastinum or entire chest may be necessary.

Infections of the retropharyngeal space in children are usually secondary to infection of the medial retropharyngeal lymph nodes. In adults, retropharyngeal space infection is most commonly the result of perforation of the posterior wall of the pharynx or esophagus. Infections of the parapharyngeal space or posterior pharyngeal wall, if unchecked, may penetrate the visceral fascia and involve the retropharyngeal space.¹² Regardless of their origin, retropharyngeal space abscesses have a characteristic "bow tie" appearance on axial images that facilitates identification.⁷ Sagittal MR images are ideal for definition of the superior and inferior extension of retropharyngeal abscesses before surgical intervention (Fig. 17–29).

The prevertebral space includes those structures (verte-

Figure 17–29. Retropharyngeal space abscess. Sagittal T2-weighted MR image demonstrates a hyperintense mass in the retropharyngeal space (asterisks) with anterior displacement of the airway. The abscess extends inferiorly to the level of the third thoracic vertebra (T3), implying involvement of the retrovisceral space rather than the danger space. (From Holliday RA, Prendergast NC: Imaging inflammatory processes of the oral cavity and suprahyoid neck. *Oral Max Surg Clin North Am* 4:215, 1992.)

bral bodies, paravertebral and scalene muscles, vertebral arteries) that are surrounded by the deep layer of the deep cervical fascia. Lying posterior to the retropharyngeal space, the prevertebral space may be further divided into anterior and posterior compartments by the attachment of the deep layer of deep cervical fascia to the transverse processes. Infections of the prevertebral space are usually secondary to vertebral infection (osteomyelitis) or posterior extension arising in the retropharyngeal space.

The carotid space is a potential space within the carotid sheath. Because little areolar tissue is present within the sheath, actual infection of the carotid space is rare. The carotid sheath, however, with its contributions from all three layers of the deep cervical fascia, is a conduit of infection from one space to another. Septic or reactive thrombosis of the internal jugular vein may produce swelling within the carotid space.¹²

Masses of Vascular Origin

Asymmetry in the diameter of the internal jugular veins is a normal variant and should not be confused with a mass (see Fig. 17–6). Tortuous arterial vessels may manifest as a pulsatile mass in the supraclavicular fossa or neck. Masses lying in close proximity to the internal or common carotid arteries may transmit normal arterial pulsations. Sectional imaging can differentiate between these "pulsatile" masses and aneurysms of the cervical arterial system.

Internal jugular vein thrombosis, most commonly secondary to central venous catheterization or intravenous drug abuse, is readily diagnosed on sectional imaging. On contrast-enhanced CT, the central portion of the thrombosed vessel is usually less dense than contrast-enhanced blood. Enhancement of the wall of the vein is often present and may extend into surrounding fascial planes.¹ A number of lesions may mimic a thrombosed vein on one or more sequential CT scans. Lesions that may be confused with a thrombosed vessel include necrotic lymph nodes, cervical abscesses, infected branchial cleft cysts, and thrombosed carotid arteries (Fig. 17–30). In most cases, careful analysis of sequential images and correlation with clinical history can distinguish venous thrombosis from other lesions.³³

In the evaluation of venous patency with MRI, care must be taken not to confuse flow-related enhancement with thrombosis. The MRI diagnosis of venous thrombosis often requires partial flip angle imaging or phase imaging to confirm findings identified on spin-echo sequences.⁴

Paragangliomas, commonly known as glomus tumors, are neoplasms of neural crest cell origin that arise within the adventitial layer of blood vessels at multiple sites in the head and neck, including the middle ear (glomus tympanicum), parapharyngeal space (glomus jugulare), and larynx. The two most common paragangliomas to present as a neck mass arise at the carotid bifurcation (carotid body tumor) and along the nodose ganglion of the vagus nerve (glomus vagale). Such a mass typically manifests as a painless slow-growing mass in the anterior triangle of the suprahyoid neck. The mass is commonly pulsatile, and a bruit may be auscultated over it.³³

The most constant feature of the glomus vagale or

Figure 17-30. Internal jugular vein thrombosis. *A*, Axial contrast-enhanced CT scan at the level of the cricoid cartilage demonstrates hypodensity with peripheral rim enhancement (*curved white arrow*) lateral to the right common carotid artery (*A*). *3*, Left common carotid artery; *IJV*, left internal jugular vein. *B*, Axial contrast-enhanced CT scan at the level of the jugular vein (*curved white arrow*) and the necrotic left internal jugular chain lymph node (*white arrow*) metastatic from the left supraglottic carcinoma (*white arrowheads*). Arteriosclerotic change is present in the common carotid arteries bilaterally (*A*).

carotid body tumor on CT scans is intense enhancement after intravenous contrast administration. Dynamic CT scanning after bolus contrast administration has been reported as a reliable method of differentiating paragangliomas from schwannomas, because the former have a vascular flow curve but the latter do not.⁴³

MRI has all but replaced dynamic CT in the imaging evaluation of suspected glomus or carotid body tumors. Paragangliomas more than 1.5 cm in diameter should demonstrate curvilinear areas of signal void representing areas of high vascular flow (Fig. 17-31).²⁵ Schwannomas, which classically are avascular lesions on angiography, do not demonstrate areas of signal void.³³

Identifying areas of signal void within a neck mass on MRI allows the confident diagnosis of paraganglioma only

if the mass is present in the correct location. Carotid body tumors arise in the juxtahyoid neck and separate the internal and external carotid arteries on sectional imaging. Glomus vagale tumors arise in the suprahyoid neck and displace the internal carotid artery anteromedially and the internal jugular vein posterolaterally. Other neck masses with areas of signal void on MRI, such as nodal metastases from renal cell or thyroid carcinoma,⁴² do not demonstrate these vascular displacements. This MRI appearance is not pathognomonic for paraganglioma and may be seen in a variety of high-flow lesions. An imaging diagnosis of paraganglioma should prompt a careful search for additional lesions because multiple glomus tumors occur in up to 10% of the general population and in up to 33% of patients with a family history of paraganglioma.²⁷

Figure 17-31. Carotid body tumor. *A*, Sagittal T1-weighted MR image demonstrates a heterogeneous mass (arrow) at the bifurcation of the common carotid artery (c) splaying the external (e) and internal (i) carotid arteries. *B*, Axial T1-weighted MR image at the level of the hyoid bone in the same patient demonstrates a right anterior triangle mass (large black arrow) with multiple internal areas of relative signal void (small black arrows).

Masses of Neural Origin

Schwannomas and neurofibromas are the most common types of neurogenic tumors found in the head and neck. Common sites for schwannomas and neurofibromas in the neck are the vagus nerve (cranial nerve X), the ventral and dorsal cervical nerve roots, the cervical sympathetic chain, and the brachial plexus. Associated motor dysfunction and pain in the distribution of a sensory nerve are inconstant clinical findings.¹⁵

Without a clinical history of neurofibromatosis, it is impossible to distinguish between these two neural masses on sectional imaging. Most neural tumors appear hypodense or isodense to skeletal muscle on noncontrast CT. These tumors tend to be hypointense or isointense to skeletal

muscle on T1-weighted MR images and variably hyperintense on T2-weighted images. Variations in the CT or MRI appearance of masses of neural origin are commonly thought to be secondary to variations in cellularity or lipid content. The enhancement pattern of neural tumors is highly variable. Intense, uniform enhancement, inhomogeneous enhancement, and lack of enhancement have all been reported. It is not unusual for an isolated schwannoma to be mistaken for a nodal mass on sectional imaging (Fig. 17-32).^{11, 18, 29,42}

The correct imaging diagnosis of a neural tumor requires a thorough knowledge of the normal anatomy of the major nerves in the neck. A tumor arising from the vagus nerve manifests as a mass in the anterior triangle, displacing the internal or common carotid artery anteromedially and the

Figure 17-32. Schwannoma. Axial contrast-enhanced CT scan at the level of the hyoid bone demonstrates a heterogeneous mass (curved white arrow) deep to the right sternocleidomastoid muscle. An initial radiographic diagnosis of nodal metastases was offered because of the location of the mass posterior to the internal jugular vein (v) and the patient's history of prior right facial melanoma.

Figure 17-33. Vagal schwannoma. Axial contrast-enhanced CT scan at the level of the thyroid notch demonstrates a predominantly low-density mass (curved white arrow) deep to the anterior margin of the right sternocleidomastoid muscle (s) that is splaying the internal jugular vein (v) and the internal carotid artery (I). e, External carotid artery.

internal jugular vein posterolaterally (Fig. 17-33).¹⁴ Neoplasms of the cervical nerve roots manifest a mass in the posterior triangle, which may extend into one of the neural foramina of the cervical spine (Fig. 17-34). Sympathetic chain tumors demonstrate a constant relationship with the longus colli muscles. Brachial plexus schwannomas and neurofibromas in the infrahyoid neck often displace the anterior scalene muscle anteriorly.³⁹

Masses of Mesenchymal Origin

Lipomas are the most common cervical neoplasms of mesenchymal origin. They typically manifest as painless, slow-growing masses, occurring most commonly in the midline of posterior neck or the posterior triangle. Their CT appearance—a homogeneous, nonenhancing mass isodense with subcutaneous fat—is diagnostic (Fig. 17-35).^{33,44} The overwhelming majority of lipomas identified on MRI are isointense to subcutaneous fat on all pulse sequences. Lipomas may or may not have a demonstrable capsule on sectional images. Liposarcomas arise from totipotent mesenchymal cells and are rarely encountered in the head and neck. Liposarcomas occur *de novo* and are not the result of malignant degeneration of preexisting lipomas. Liposarcomas are differentiated from lipomas on the basis of their faster growth rate and the presence of soft tissue and mucoid elements admixed with fat on sectional imaging.

None of the remaining mesenchymal tumors can be confidently diagnosed by sectional imaging alone. These rare lesions tend to appear largely isodense or isointense to skeletal muscle on noncontrast CT or T1-weighted MR images. Inhomogeneous contrast enhancement is usually observed. Rhabdomyosarcoma and other malignant mesenchymal tumors tend to destroy bone and distort soft tissue planes.¹⁶ Desmoids and other benign mesenchymal tumors tend to have sharply circumscribed borders and typically do not infiltrate adjacent soft tissue or destroy bone.⁸ The primary role of imaging is one of lesion localization, not lesion characterization.

Masses Arising from the Aerodigestive Tract

Masses may be detected on sectional images of the neck that represent cervical extensions of diseases arising within the oral cavity, larynx, or hypopharynx. A *ranula* is a mucous retention cyst that arises from an obstructed sublingual or minor salivary gland in the floor of the mouth. Simple ranulas are limited to the sublingual space and are seen as intraoral mass lesions. Diving (or plunging) ranulas herniate through or around the mylohyoid muscle and extend into the submandibular triangle. Diving ranulas have been likened to pancreatic pseudocysts because they both contain proteolytic enzymes that allow the mass to infiltrate adjacent tissues.

On CT, ranulas are thin-walled unilocular homogeneous cystic lesions. As with congenital cystic masses, prior infection or surgical intervention results in septations or irregular rim enhancement (Fig. 17-36).⁸ On MRI, ranulas are typically hypointense to skeletal muscle on T1-weighted images and isointense to cerebrospinal fluid on T2-weighted images. An imaging diagnosis of diving ranula should be considered only when the lesion abuts or involves the sublingual space. The multiplanar capacity of MRI may facilitate documentation of a *tail of tissue* within the floor of mouth.¹⁸

A laryngocele is an abnormal dilatation of the saccule (appendix) of the laryngeal ventricle. Although a small proportion of laryngoceles are congenital, the majority are the result of chronic increases in intralaryngeal pressure. Neoplasms or localized inflammation and edema may partially obstruct the ventricle. The resulting ball-valve mechanism traps air within the saccule. Mucus produced by the respiratory epithelium of the ventricle may result in a fluid-filled laryngocele (*laryngeal mucocele*). Internal laryngoceles are limited to the paralaryngeal space. External or combined internal and external laryngoceles extend from the paralaryngeal space into the anterior triangle of the neck via fenestrations in the thyrohyoid membrane.⁹ On CT or MRI, the external component of a laryngocele appears as

Figure 17-34. Dorsal cervical nerve root schwannoma. *A*, Axial contrast-enhanced CT scan at the level of the thyroid cartilages demonstrates a rim-enhancing solid posterior triangle mass (*asterisk*) deep to the left sternocleidomastoid muscle (*S*). On this single image, differentiation of neural tumor from enhancing lymph node would be impossible. *B*, Axial contrast-enhanced CT scan at the level of the hyoid bone demonstrates that the mass (*asterisk*) involves the neural foramen (*arrows*), allowing the correct radiologic diagnosis of neural tumor.

Figure 17-35. Lipoma. Axial contrast-enhanced CT image at the level of the thyroid notch in an adolescent patient demonstrates a uniform-fat-density mass in the anterior triangle (*L*), superficial to the right strap muscles (*S*). Imaging was performed to exclude the possibility of thyroglossal duct cyst. Compare with Figure 17-22.

Figure 17-36. Ranula. A, Axial contrast-enhanced CT scan at the level of the thyroid cartilage demonstrates a unilocular cystic anterior triangle mass deforming the anterior margin of the right sternocleidomastoid muscle (S). On the basis of this single image, differential diagnosis would include second branchial cleft cyst, lymphangioma, and necrotic lymph node. Thyroglossal duct cyst should be excluded from the differential diagnosis because the mass is extrinsic to the strap muscles (*asterisks*). B, Axial contrast-enhanced CT image at the level of the mandible demonstrates the origin of the ranula in the posterior oral cavity, medial to the enhancing mylohyoid muscle (*arrows*). M, Right mylohyoid muscle; G, right submandibular gland.

Figure 17-37. Combined laryngocele. Axial contrast-enhanced CT image at the level of the hyoid bone demonstrates a thin-walled, air-filled, right anterior triangle mass (*white arrows*) in direct continuity with the left paralaryngeal space. *Curved arrow*, right paralaryngeal space.

a thin-rimmed, fluid-filled or air-filled mass directly lateral to the thyrohyoid membrane. Continuity with the internal component can be demonstrated on axial or direct coronal images (Fig. 17-37).

A *pharyngocele* is an abnormal dilatation of the piriform sinus, which may also herniate through the thyrohyoid membrane to manifest in the anterior triangle. The less common pharyngocele is differentiated from a laryngocele by the demonstration of continuity with the piriform sinus rather than the laryngeal ventricle. Neoplasms or abscesses involving the apex of the piriform sinus may extend into the anterior triangle of the infrahyoid neck through the cricothyroid membrane.³⁵

The Larynx

Hugh D. Curtin

Imaging of the larynx can be an extremely difficult endeavor. The anatomy is complex. The target moves with every breath and every swallow. In certain situations, however, imaging addresses questions that the clinician has difficulty in answering and can make a considerable difference in treatment planning.

Imaging must be considered in light of the capabilities of modern endoscopy.^{1, 10, 18} As the technology of imaging has progressed, so too has the instrumentation available for direct visualization. The mucosa can be examined thoroughly. To be relevant, imaging must provide information that cannot be obtained by direct visualization. Thus, the usual intent of the radiologist is to evaluate the deeper tissues. In some cases, a bulky lesion of the upper larynx may block the view of the lower larynx, and imaging may assist in defining caudal extent of disease.

The radiologist seeking to assess laryngeal pathology obviously must be familiar with the anatomy. The disease processes and their behavior are important. The radiologist must also be familiar with the available therapeutic options to emphasize the information that will be important in making clinical decisions.

This chapter begins with a discussion of anatomy, including the normal appearance in the various imaging planes. A brief mention of technical considerations in applying magnetic resonance imaging (MRI) and computed tomography (CT) scans to the task of examining the larynx is followed by descriptions of imaging of various pathologic conditions. The important clinical considerations in each disease are stressed.

Anatomy

The larynx is a system of mucosal folds supported by a cartilaginous framework.¹⁵ Tension and movement of the mucosal folds are accomplished by the actions of small muscles pulling against the cartilaginous framework.

The clinical organization of the larynx emphasizes the mucosal anatomy, making the mucosa a good starting point for the present discussion. This concept is particularly important to the radiologist because descriptions of tumors must encompass the relationship to the landmarks on the mucosal surface.

From the superior view (the view of the endoscopist), the first landmark seen is the *epiglottis*. The upper edge of the epiglottis represents the most superior limit of the larynx. The epiglottis is the anterior boundary of the entrance into the larynx. Anteriorly, two small sulci—the *valleculae*—separate the free portion of the epiglottis from the base of the tongue (Fig. 18-1). From the lateral margin of the epiglottis, the aryepiglottic (AE) folds curve around

to the small interarytenoid notch. Together these structures complete the boundaries of the airway at the entrance into the larynx.

The inner mucosal surface of the larynx, or *endolarynx*, can be thought of as the working part of the organ. Two prominent parallel folds stretch from front to back along the lateral aspect of each side of the airway (Figs. 18-2 and 18-3; see also Fig. 18-1). These are the true and false vocal cords or folds, and they are in the horizontal plane. The *true cord* (the *glottis*) is the key functional component in the generation of voice and has a fine edge at the medial margin. The more superiorly placed *false vocal fold* has a more blunted medial edge.

Separating these two folds is one of the most important landmarks in the larynx. The *ventricle* is a thin cleft between the *true cord* and the *false cord*, stretching from the most anterior limit of the cord almost to the posterior limit of the larynx.

Above the false cord the mucosa sweeps upward and outward to the *aryepiglottic (AE) folds*. Inferiorly, the mucosa covering of the true cord sweeps outward into the subglottic area, eventually merging smoothly with the mucosa of the trachea.

A final important mucosal landmark is the *anterior commissure*, the point where the true vocal cords converge anteriorly to attach to the inner (posterior) surface of the anterior angle of the thyroid cartilage.

The three parallel structures—the true cord, the false cord, and the ventricle—organize the larynx into three regions: the supraglottis, the glottis, and the subglottis.

The true cord is the glottis. The glottic region of the larynx extends from the upper surface of the true cord to a line somewhat arbitrarily chosen as being 1 cm below the level of the ventricle. The subglottic region is between this arbitrary line and the inferior edge of the cricoid cartilage, the lower margin of the larynx. There is no defined mucosal structure representing the exact boundary or separation of the glottic and subglottic regions.

The supraglottic region is the part of the larynx that is above the ventricle. This region includes the false cords, the epiglottis, and the AE folds.

Laryngeal Skeleton

The laryngeal cartilages are the supporting framework of the larynx. The major cartilages include the cricoid, the thyroid, the arytenoid, and the epiglottic. The smaller cartilages, the corniculate and the cuneiform, reside in the aryepiglottic fold and are not of particular importance to the radiologist.

The *cricoid cartilage* is the foundation of the larynx and

Figure 18-1. The larynx is split sagittally, with a view of the lateral wall of the airway. The mucosa over the true cord (1) has been removed to show the thyroarytenoid muscle (TAM), which extends from the arytenoid to the thyroid cartilage. The upper edge of the muscle (arrow) indicates the level of the ventricle. The false cord (2) is just above the ventricle. E, epiglottis; F, preepiglottic fat; H, hyoid; T, thyroid cartilage; V, vallecula. (From Curtin HD: *The larynx*. In Som PM, Bergeron RT [eds]: *Head and Neck Imaging*, 2nd ed. St. Louis, Mosby-Year Book, 1991.)

is the only complete ring. The posterior part is larger than the anterior, giving the cartilage the appearance of a signet ring facing posteriorly. The lower margin of the cricoid cartilage represents the lower margin of the larynx.

The *thyroid* and the *arytenoid cartilages* articulate with the cricoid. The thyroid cartilage is large and can be thought of as forming a shield for most of the inner larynx. The arytenoid cartilages perch on the superior edge of the posterior cricoid.

The arytenoid cartilage spans the ventricle. The upper arytenoid is at the level of the supraglottic larynx. The lower arytenoid has a pointed process anteriorly, called the vocal process. Because of its characteristic shape and position, the arytenoid cartilage can help localize the ventricle on axial scanning. This is most helpful on CT scans, where the vocal process may be directly visualized. The upper margin of the arytenoid is at the level of the lower false cord just above the ventricle. The vocal process is at the level of the true cord just below the ventricle. Indeed,

Figure 18-2. Sagittal T1-weighted MRI study. This sagittal slice is just off midline. The slice shows the anterior part of the true cord (1) and false cord (2) separated by the low signal intensity of the laryngeal ventricle (arrowhead). The axial image plane should be along the ventricle, as indicated by the white line. The preepiglottic fat is shown by an arrow. E, epiglottis; H, hyoid. (From Curtin HD: *MR and CT of the larynx*. In Thrall JH [ed]: *Current Practice of Radiology*, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

Figure 18-3. Coronal T1-weighted image. This slice would be perpendicular to the white line in Figure 18-2 at the level of 1 and 2. The thyroarytenoid muscle (1) makes up the bulk of the true cord. The paraglottic space at the level of the false cord (2) is filled predominantly with fat. The ventricle is the air-filled slit (arrowhead) between the two. T, thyroid cartilage. (From Curtin HD: *MR and CT of the larynx*. In Thrall JH [ed]: *Current Practice of Radiology*, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

the vocal ligament, which represents the medial margin of the true cord, attaches to the vocal process.

The epiglottic cartilage, except for its superior tip, is totally contained within the external framework of the larynx. This cartilage is made up of elastic fibrocartilage and does not calcify. Grossly, this cartilage has multiple perforations resembling more a mesh than a solid plate, and the epiglottic cartilage is thus not a major barrier to tumor spread. Inferiorly, the epiglottic cartilage is connected to the inner surface of the anterior part of the thyroid cartilage by the thyroepiglottic ligament.

Muscles and Ligaments

The cartilages are connected by a system of muscles and ligaments. Several muscles are mentioned in the remainder of the chapter. One deserves special attention. The *thyroarytenoid muscle* (TAM) stretches from the arytenoid cartilage to the inner surface of the anterior thyroid cartilage (Fig. 18-4; see Fig. 18-1). This muscle parallels the true cord and makes up the bulk of the true cord.

The cricothyroid and thyrohyoid ligaments span the greater part of the intervals between the cricoid cartilage, the thyroid cartilage, and the hyoid bone and represent, along with the cartilages, the outer limits of the larynx.

Two membranes are found just deep to the mucosa. The conus elasticus (also called the *cricovocal ligament* or *lateral cricothyroid ligament*) stretches from the vocal ligament to the upper margin of the cricoid cartilage. Some descriptions indicate the membrane attaching to the inner

surface of the ring as well. This membrane or fascial layer merges with the anterior cricothyroid ligament in the anterior midline.

A similar structure is seen in the supraglottic larynx. A thin ligament called the *ventricular ligament* is found in the lower margin of the false cord and the quadrangular membrane sweeps superiorly from the ventricular ligament terminating in the AE fold.

The fan-shaped hyoepiglottic ligament stretches from the epiglottis to the hyoid bone and divides the supraglottic larynx into a superior (suprahyoepiglottic) and an inferior (infrahyoepiglottic) area.²⁷

Spaces

The paraglottic space and the preepiglottic space are situated between the mucosal surface and the cartilaginous outer limit of the larynx.

The paraglottic space is found laterally and represents much of the soft tissue wall of the larynx (Figs. 18-5 and 18-6). Although descriptions of the paraglottic space vary, I am using Tucker and Smith's original descriptions,²⁵ with the medial boundary represented by the conus elasticus and quadrangular membrane. The lateral boundary is the external skeleton of the larynx, formed predominantly by the inner cortex of the thyroid cartilage. At the level of the supraglottic larynx, the paraglottic space is filled mostly with fat. Below the ventricle, the TAM fills the paraglottic region.

A small recess of the ventricle, called the *laryngeal saccule* or *appendix*, extends upward into the paraglottic space of the supraglottic larynx. This structure is within the paraglottic fat lateral to the quadrangular membrane.

The preepiglottic space is between the epiglottis posteriorly and the thyroid cartilage and thyrohyoid membrane anteriorly.

The hyoepiglottic ligament forms the roof of the preepiglottic and paraglottic spaces.

Imaging Considerations

Although CT scanning is limited to the axial plane, it has the advantage of fast imaging speed. The advent of multidetector CT represents a significant improvement in the application to the larynx.⁶ The scan is faster and thus allows the entire larynx to be covered in a single breath-hold. The thinner-slice thickness allows multiplanar reformatted images comparable in quality to direct imaging.

At present, magnetic resonance imaging (MRI) is better at differentiating various soft tissues compared with CT. MRI may allow better analysis of potential cartilage invasion or improved definition of the tumor muscle interface.

Motion artifact is a significant problem in imaging of the larynx. CT scanning tries to avoid the problem by its use of fast imaging. The spiral acquisition may cover the larynx in 10 to 20 seconds. The examination can be performed during slow, shallow respiration, or the scan can be done with the breath held.

More elaborate schemes are required for MRI studies.

Figure 18-4. View from above, looking down at the skeletonized larynx. The thyroarytenoid muscle (M) is seen stretching from the arytenoid to the thyroid cartilage. Arrow indicates the point where paraglottic spread of tumor is expected to intersect the lateral cord. The opposite side shows the vocal ligament stretching from the vocal process of arytenoid to the thyroid cartilage. A, arytenoid; C, cricoid. (From Curtin HD: MR and CT of the larynx. In Thrall JH [ed]: *Current Practice of Radiology*, 3rd ed. St. Louis, Mosby-Year Book, 1994.)

Figure 18-5. Axial CT through the larynx, with contrast from superior to inferior.

A, Supraglottic larynx (level of the upper thyroid cartilage). Most of the wall of the larynx is fat density. E, epiglottis; C, carotid artery; J, jugular vein; PES, preepiglottic space.

B, Supraglottic larynx inferior to that shown in A. The paraglottic space (arrow) is filled with fat density. An arrowhead represents the aryepiglottic fold. SCM, sternocleidomastoid muscle; T, thyroid cartilage.
